The anticrotalic serum that he has elaborated he believes is specific. At the same time he has had occasion to test Calmette's cobra antivenene, which, it will be remembered, that investigator claims is useful in antidoting not only cobra venom, but other venoms as well. In his investigations Noguchi believes he has demonstrated that Calmette's serum is certainly not of any

value in *Crotalus* poisoning and he casts grave doubt on its value even in cobra poisoning.

Should subsequent study substantiate Noguchi's claims there will be brought to successful fruition a long line of researches which have been initiated, fostered and finally announced as completed by our venerable Nestor of American Physicians, S. Weir Mitchell.

GASTRIC DILATATION AND TETANY.

Subjects which are relatively rare of occurrence are necessarily put on the shelf while others more frequently brought to the notice of the practitioner of medicine and of surgery are exploited and placed upon a firm basis of clinical entity. The subject of tetany has long been among those whose fate it has been to be side-tracked, and it is only in recent times that any persistent efforts have been made to understand this symptom or this disease whichever it may prove to be.

It is true that Kussmaul, so far back as 1869, recorded observations made on the form of tetany which he believed to be connected with gastric dilatation. Later on, Trevelyan, Bouveret and others conducted experiments on this rather complex train of symptoms, but all in all, the subject has been relatively neglected.

Osler recognizes a large number of forms, prominent among which are epidemic or, as it is sometimes called, rheumatic tetany. Trousseau mentions a form of tetany associated with debility following lactation and chronic diarrhea. He called it "nurses' contracture." It may be a sequel of thyroidectomy. "True tetany," Osler continues, "in this country, is extremely rare, seventy-two cases only having been collected." Lastly, he states, "There is a form of tetany which is associated with dilatation of the stomach, particularly after the organ has been washed out. The nature of the disease is unknown; certain forms depend undoubtedly on loss of the function of the thyroid gland." In his classic description of dilatation of the stomach, Osler says: "A very remarkable symptom, which occurs occasionally, is tetany, first described by Kussmaul." It is thus seen that our recognized medical authority is confessedly in the dark as to the etiology and the treatment of tetany in general and particularly of the form which arises from gastric dilatation.

That the entire subject of tetany has not received the attention which recent observations might seem to show it to deserve is to be found in the fact that it has received no place whatsoever in the index of Park's Surgery. Rose and Carless, in their Manual of Surgery, make no mention whatsoever of the only form which recent surgical advance seems to place in the realm of diseases curable by operative intervention.

Holt gives the subject a rather wide consideration. He says that it is rare, stating that he commonly sees about five cases a year. He thinks that it occasionally occurs as a primary disease, being frequently associated with rickets, chronic diarrhea, or marasmus. The most frequent exciting cause, he ascribes to some irritation of the gastro-enteric tract. This is the only suggestion or hint thrown out by this author that the stomach may, under certain conditions, be the exciting factor. He did not, at the time of writing, consider it of sufficient importance to give it special mention.

It has recently been shown at the Surgical Laboratory of Columbia that obstruction to the gut at or near the pylorus will, in the case of dogs, result in their death with tetanoid symptoms, which develop in from twenty-four to thirty-six hours. It is stated on very good authority that a cord can be tied around the gut of a dog tight enough to occlude the opening, not alone without causing death, but apparently without giving the animal the least inconvenience, if such cord be tied at some point well below the pylorus. Such a suture will not only not result in tetany, but will actually be passed with the feces after a short time, and the point of its insertion will be indistinguishable from the rest of the gut. The exact location in the gut where such obliteration will cause tetany has not yet been definitely determined.

In view of the awakening interest in the matter of gastric dilatation and other lesions, an article contributed by John H. Cunningham, Jr., in the April *Annals of Surgery*, is of more than timely interest. He writes that the symptom, tetany dependent upon gastric dilatation, and known as gastric tetany, is to be differentiated from the tetanic spasms occurring in gastro-enteritis, pregnancy, thyroidectomy, the puerperal state, acute fevers, carpopedal spasms, and from those produced by toxic substances and diseases of the central and peripheral nervous system. Gastric tetany is usually dependent upon pyloric stenosis and associated stasis and hyperchlorhydria. The stenosis is usually benign, the result of ulceration, or, as is often the case with such cicatrices, it may have passed over into a malignant condition.

The first symptom of tetany usually consists of a pricking and numbness in the hand. There is no definite sign by which this special form of tetany differs from other varieties, and the symptoms are in general well known. Bouveret and Devic are reported to have succeeded in isolating a substance soluble in alcohol which seemed closely allied to syntonin in three cases of tetany with gastric dilatation. When injected into the circulation of animals, this product induced general convulsions. Other experimenters have, however, failed to reproduce these findings. Albuminuria has usually been reported in cases of gastric tetany, although there are no recorded post-mortem evidences of renal involvement, and albumin has not been unknown in other forms of tetany.

The prognosis, as given uniformly by authors the world over, is startlingly high, the mortality rate being about 88 per cent.

Until recent years the treatment has been almost entirely medical in all reported cases of gastric tetany. After a careful search of the surgical literature on the subject, Cunningham finds that the operative treatment shows a mortality of only 37.5 per cent. Medical treatment can be briefly summed up in the aphorism, "Nurse, feed and stimulate," to which may be added free lavage of the stomach.

The surgical treatment consists in the simple performance of gastro-enterostomy. Why some cases—an unknown but small percentage of the large number known to be suffering from gastric dilatation—should develop tetany is far beyond our present knowledge. The cause is not the degree of the dilatation or the extent of pyloric obstruction, or the food consumed. Neither has it been shown to be due to the presence of any unusual organism within the dilated organ,—it is one of the enigmas remaining to be solved.

If, however, our appetite for academic demonstrations and proofs in this matter has not yet been satisfied, there is much material of a practical nature to be gleaned from such papers as the one under discussion. From the remarkable history of the case cited by the author, it is evident that the man passed through a great many general hospitals in various eastern cities of the United States; that he was seen by many able medical consultants; that their treatment consisted in rest and lavage; that he became progressively worse; that had the medical treatment continued, he would unquestionably have died. This, rather than the problem as to the presence of some unusual substance in the decomposing material of the stomach, is of interest to the general practitioner. The question which arises in his mind is, What is to be done with cases of tetany which are shown to be due to gastric dilatation?

There is abundant evidence to demonstrate that under medical treatment three-quarters of them will die,—a large percentage from suffocation. Under surgical treatment, somewhat less than one-third perish, and by a relatively painless death. When methods for performing gastro-enterostomy or some other adequate means of drainage are perfected, as they will be within the next ten years, this percentage may be more than cut in two. Indeed, it is conservatively high for the present status of the operation, from ten to fifteen per cent. being claimed by many operators.

ECHOES AND NEWS.

NEW YORK.

Danger in Salads.—At the annual dinner of the Faculty of the New York Polyclinic, given on Monday evening, May 9, Professor Morris Manges, in discussing the question of the contamination of oysters with typhoid germs, said, "There is danger that in reviling the oyster we may overlook greater dangers of infection. Housewives should see to it that celery and salads are carefully washed before they are served."

Hospital Positions.—Graduates in medicine who desire to substitute for members of the house staffs of Bellevue, Gouverneur, Harlem and Fordham hospitals, absent on leave, may apply with credentials giving time and place of graduation, hospital experience and references, to the Superintendent of Bellevue Hospital, First avenue and East Twenty-sixth street.

Progress of the Joint Committee for Consolidation.—At a meeting of the Joint Committee of Conference held at the New York Academy of Medicine, May 6, 1904, the following resolutions were passed:

Resolved, That the President and the Secretary of the Joint Committee of Conference, be authorized and directed to make a certificate provided for in the tenth paragraph of the agreement, and the Counsel of the Committee be directed to proceed with diligence to obtain a final order for the consolidation of the corporations, pursuant to the terms of the agreement, and that the form of the certificate to be made by the Chairman and the Secretary, be in the form of the draft certificate submitted to this Committee, which is as follows:

"Supreme Court, New York County.—In the matter of the application of the Medical Society of the State of New York, and the New York State Medical Association, for an order consolidating the said corporations, pursuant to the Act, Chapter 1, of the Laws of 1904.

"This is to certify that the Joint Committee of Conference mentioned in the agreement for the consolidation of the Medical Society of the State of New York and The New York State Medical Association, which agreement was unanimously adopted by the Medical Society of the State of New York, at its annual meeting at Albany, on January 26, 1904, and by The New York State Medical Association at a special meeting of the Association held in New York, on March 21, 1904, has not ordered the submission of said agreement or of any questions in connection therewith, to the County Medical

Societies or Associations, referred to in said agreement, and that the conditions precedent to an application to the Court for an order consolidating the Medical Society of the State of New York and The New York State Medical Association have been fully complied with; and this certificate is made pursuant to the "Tenth" paragraph of said agreement.

"In witness thereof, the undersigned, Abraham Jacobi, Chairman of the Joint Committee of Conference and Wisner R. Townsend, Secretary of the Joint Committee of Conference, do hereunto subscribe their names at the City of New York, this.....day of May, 1904."

Thirty out of thirty-five County Associations have ratified. One, Onondaga has refused to ratify, four have not yet reported. The Associations that have ratified represent a membership of 1,711, and those that have not acted a membership of 42. The one refusing to ratify has 14 members. Ratifications have been received from 47 out of the 51 County Societies, four have not yet acted. Those which have ratified represent a membership of 5,569. Those which have not yet acted a membership of 164.

According to the agreement, Article 10, declares "that whenever the Chairman and Secretary of the Joint Conference Committee shall certify that the conditions precedent to an application to the Court have been fully complied with, the Presidents of the respective corporations shall, and they are hereby authorized and required in the name and behalf of their respective corporations to petition the Supreme Court for an order to consolidate in accordance with the terms thereof. Therefore all County Associations and Societies that have not ratified will be asked to appear before the Court at a specified date appointed by the Court, and show cause why the consolidation should not be completed according to the terms of the agreement, despite their failure to ratify.

Hospital Appointments.—The following is the list for the past week: Metropolitan Hospital (Blackwell's Island), J. B. Pentz. Beth Israel, H. Finkelstein, D. Katz, K. Schliwek, M. Dattelbaum.

Navy Doctors Wanted.—Dr. R. E. Marmion, Medical Director of the U. S. Navy, and President of the Navy Medical Examining Board, spoke to the students at the College of Physicians and Surgeons on May 4 upon the advantages of going into the Government service. In previous years it has been difficult to get good men to enter because of the low status of physicians in the rank of officers, and consequently out of 150 places it was common to find 50 of them vacant. Since 1898, however, this aspect of the situation has changed, and a physician now holds positive rank with a chance for promotion. Upon the consent of the Secretary of the Navy one is allowed to come before this Naval Examining Board. He must swear that he is between the ages of twenty-one and thirty years, must be a citizen of the United States and must fill out all the necessary forms in his own handwriting. The examination is held at Washington and occupies nine days, during which the candidate first undergoes a physical test. Failure to pass this debars from further examination. Dr. Marmion stated emphatically that a "pull" is unnecessary and is often quite useless, for each man must stand on the merits he can display before the examiners. For those who pass and are properly commissioned there is a special Naval Medical School at Annapolis where the candidates study for five months previous to actual service. Here they are taught naval law, military surgery, military medicine and tropical diseases, hygiene and quarantine, broad sword and other physical exercises, and are obliged to spend seven and a half hours a week in the bacteriological laboratory. After this course is completed each man is assigned to his post of duty. The salaries range from $1,700 to $4,500 and are likely to be raised 50 per cent. at the next session of Congress. After three years' work in the position to which he was originally assigned a naval doctor may again come before the Board for an examination for promotion.

Professor Bull's Farewell.—On May 4 Prof. William T. Bull delivered his last lecture at the College of Physicians and Surgeons. As a few minutes of the hour were left he followed the custom of those who had seen a long course of service in the college by making a few remarks in laying down the burden and honors of his position. He felt that the time had come in the course of an agreeable voyage to part with pleasant company. The many years during which he had lectured in surgery had been full of pleasure and profit, to himself at least, because the audiences were always so interested and so responsive. Many a time he has said and wishes again to repeat the statement that medical students are the best of any class of professional students, because they so unreservedly give their time, energy and enthusiasm to the work in hand. It is no uncommon thing to find men who were known to be loafers in their respective universities come into a medical school and set up for themselves a new record, a new standard and a spirit of sincerity and devotion formerly entirely foreign to their natures. The spirit of the students had always affected and inspired him to do more and better work in this beloved profession. The present occasion was not a separation but the beginning of a new relationship in which the men before him were to go out into the world and add a bit to their knowledge of disease, and in this respect he hopes henceforth to find leisure and become a fellow-student. He was glad that his successor and those associated with him were graduates from these benches, and felt sure that they would receive the same kind of consideration from the students that he himself had always experienced. When Prof. Bull had finished F. D. H. Coerr, representing the third and fourth year classes, in a very fitting speech presented a silver loving cup. In replying Dr. Bull said that he wished for the voice, hands, feet, and lungs of those before him in order that he might show his gratification. Never before had he received such a "send-off," save possibly once when in college he was disciplined by the Faculty and given a leave of absence. He wished all before him a pleasant vacation and an affectionate farewell.

Bust of Dr. Helmuth.—A bust of the late Dr. William Tod Helmuth was unveiled in the surgical amphitheatre of Flower Hospital, in connection with the commencement exercises of the New York Homeopathic Medical College, which occurred last Thursday.

Low Temperature of Milk Required.—A letter sent out on May 10 by Dr. Darlington, Health Commissioner, to all milk dealers and railroads entering the city, says that all milk, the temperature of which is higher than 50° F. will be seized and destroyed, and the offending persons prosecuted. The letter refers to Section 53 of the Sanitary Code, relating to adulterated milk, and said that hereafter that section would be enforced. When he announced that the letter had been issued, Dr. Darlington said that more than 2,000,000 quarts of milk come into the city daily, and that fully 4,000,000 persons are supplied. He believed, he said, that 25 per cent. of the deaths among babies in the summer was due to milk rendered impure by its high temperature. As long as the temperature of milk is kept below 50 degrees, there is little, if any, danger, he said, but when the temperature rises to 55 or 60 degrees, the germs split up and multiply with great rapidity. All milk above

50 degrees will be destroyed, and violators will be liable to a fine of from $25 to $500. Dr. Darlington has had his milk inspectors equipped with State authority, and they are investigating the dairies throughout the State.

PHILADELPHIA.

Address by Dr. Freeman.—Dr. Rowland G. Freeman, of New York, addressed the Philadelphia Pediatric Society at the meeting of May 10 on "The Feeding and Care of Children After the First Year." At the close of the meeting a reception was tendered Dr. Freeman at the Hotel Stenton.

Nurse Added to Staff of Normal School.—An innovation by the Keystone State Normal School at Kutztown, Pa., is the addition to the staff of a trained nurse who will attend to the wants of students that may be taken ill while at the school. Miss Mabel Brown, formerly head nurse at the Allentown hospital, has been selected for the place.

Trained Nurses in Convention.—The seventh annual convention of the Nurses' Associated Alumnæ of the United States was held in the Drexel Institute, May 12 to 14. The Association and its affiliated societies control a membership of about 5,000 nurses. One of the chief objects is to secure state registration of trained nurses.

Health Report.—The number of cases of typhoid fever for the week ending May 7, though abnormally high, continues the steady decrease that has obtained during the past four weeks; in this time the new cases have fallen from 389 to 277. The total number for the year is now 3,711. A large number of merchants, manufacturers and others to whom the Trades League sent letters asking them to provide filtered, boiled or spring water for the use of their employees have made favorable reply. During the week quoted, the deaths from pneumonia equaled those from pulmonary tuberculosis, there being 86 of each.

Pennsylvania Society for the Prevention of Tuberculosis.—At the annual meeting held May 4, Dr. Howard S. Anders was elected President and Dr. Ward Brinton, Secretary. Dr. Anders decried the use in street cars of the old-fashioned velvet cushions, saying that they contain typhoid, tubercle and other bacilli. He also stated that the society had protested against the methods of street cleaning now in vogue and had suggested that this be done early in the morning when but few people were on the street; the bureau of street cleaning has as yet made no reply. The society has been informed by the authorities that it is difficult to enforce the anti-spitting ordinance as the policemen pay but little attention to it; councils will not make an appropriation for maintaining special officers for this purpose.

Illegal Practitioners.—Several arrests have been made as a result of the stand recently taken by several of the local societies and the State Board of Medical Examiners. One druggist has been held for court; he is a graduate physician but has failed twice to pass the State Board. The head of an electrotherapeutic institute was arrested for obtaining money by false pretense; he was released by the magistrate, who held that the promise of cure by electricity was not illegal. A member of the senior class of Medico-Chirurgical College has been expelled by that institution for practicing medicine illegally and has since been arrested.

Large Hospital Deficits.—Nearly all the hospitals in the city are confronted by unusually large deficits for the past year. The largest is that of the Pennsylvania hospital which was run at a loss of $33,692.90. The deficit is in every instance attributed largely to the increased cost of foodstuffs, fuel and other necessary supplies. The unusually large number of typhoid fever patients was also a drain on many of the institutions. In reality many of the hospitals are beggaring themselves by the indiscriminate treatment of an increasing number of free patients. It is particularly unfortunate that the large deficits should come at the time when so many of the hospitals are needing new buildings and equipment.

Gastro-enterostomy for Supposed Carcinoma.—At the Philadelphia Academy of Surgery, May 2, Dr. John H. Gibbon reported a case of supposed carcinomatous obstruction of the pylorus nine months after posterior gastro-enterostomy and exhibited the patient. Dr. Gibbon said he reported the case for three reasons: (1) To show that it was a difficult matter to differentiate gastric ulcer from gastric carcinoma when the ulcer is infiltrated, even when the abdomen has been opened; (2) to show the advantage of doing gastro-enterostomy even in the presence of apparently hopeless malignant disease; (3) to explain why recovery occurs after supposed cases of gastric cancer. The patient was a woman thirty-eight years of age who had exhibited gastric symptoms for some eight years. Benign obstruction of the pylorus was diagnosed. When the abdomen was opened a pyloric mass the size of a lemon was found and the glands in the lesser omentum were enlarged. The diagnosis was changed to that of malignant disease and gastro-enterostomy was done with the intention of doing later a partial gastrectomy if the condition of the patient so improved as to warrant it. The patient has markedly improved since the operation; she has gained about 30 pounds and is now the picture of health. The after-history of this patient leaves no doubt in the mind of Dr. Gibbon that he was dealing with an indurated gastric ulcer.

Obituary.—Dr. William Barton Hopkins, the well-known surgeon, died on May 4 after an illness of little more than forty-eight hours. He was on his way south to join a friend on a pleasure tour when he was seized with cholera morbus and survived but a short time after reaching home. Dr. Hopkins was surgeon to the Pennsylvania Hospital and to the Orthopedic Hospital and Infirmary of Nervous Diseases; for years he was surgeon to the Episcopal Hospital. His surgical writings, particularly his book on Fractures, have been widely read. Dr. Hopkins was prominent socially and was a member of the Rittenhouse, Country, New York Yacht, Corinthian Yacht, and numerous medical clubs. He was a grandson of Dr. Samuel Hopkins and a grandnephew of Dr. John Rhea Barton.

Dr. Roberts Bartholow, professor emeritus of materia medica and therapeutics and hygiene in Jefferson Medical College, and widely known as an author of medical works, died last Tuesday at his home, 1527 Locust street, Philadelphia. He was seventy-three years old. Dr. Bartholow was born in Maryland and was graduated in medicine from the University of Maryland in 1852. He served as medical director in the army, in Utah, in 1857. During the Civil War he was first medical director on General McClellan's staff, and later chief of various army hospitals. After serving on the faculty of Ohio Medical College he came to Philadelphia, and for many years was an active member of the Jefferson College faculty. He belonged to many learned societies at home and abroad.

CHICAGO.

Examination of Medical Officers Held.—An examination of candidates for medical officers for the Illinois National Guard was held at Rush Medical College, April 30. Eight candidates took the examination; of these, five were for the naval reserves, two were dental surgeons, and one examination was promotional. The range of subjects included anatomy, physiology, chemistry, materia medica and therapeutics, pathology and bacteriology, hygiene and sanitation, military surgery and practice of medicine. The naval candidates were examined on naval hygiene and sanitation, and the dentists on anatomy, physiology and dentistry.

Death Rate in April.—The death rate for last month was, with three exceptions, the lowest on record. The 2,486 deaths reported during the month represent an annual death rate of 15.68 per 1,000. The great reduction, as compared with 1903, is in the deaths of children under five, and amounts to nearly 30 per cent.

Honor Founder of Hospital.—Celebrating the occupancy of the new dispensary of the Chicago Lying-in Hospital, the nurses and internes presented a gold loving cup to Dr. Joseph B. De Lee, founder of the hospital.

Branch Hospitals.—Hospitals in several different sections of the city, built by the County and maintained as branches of the County Hospital, are proposed by President Henry G. Foreman, President of the County Board. The plan was outlined at a recent meeting, and was favorably received by the members. The plan is to submit to the people of the County at the election next fall the question of a bond issue for the creation of three branch hospitals, and the construction of new fireproof buildings in all instances where the County does not possess fireproof buildings more than two stories in height.

Arteriosclerosis in Its Relation to Life Insurance.—Dr. Wm. Cuthbertson read a paper on this subject before a recent meeting of the Chicago Medical Examiners' Association. Among other things, he stated that when once this disease was established, its onward march was sure, and its arrest or cure was not possible by any therapeutic measures known to medical science at the present day. There were remedial measures at the command of the profession, such as nitroglycerin, the iodide of potash, etc., which would mitigate the severity of the symptoms and prolong life for a longer or shorter period; but this fact did not lower the mortality rate, or which was of more importance to the profession, decrease the risk or lower the expense of the companies in whose employ physicians were. Heretofore too little attention had been paid to this disease, both by the internists, and by medical examiners, and the fault lay in the early medical training of physicians, which led them to look upon arteriosclerosis only as a disease of middle or particularly late life, presumably associated with intemperate habits and all that went with them, such as syphilis, undue exposure, etc. Medical literature of recent years showed an awakened interest in this form of disease, and augured well for the intelligent, studious examiner, to be amply forewarned and forearmed in regard to a malady which to the author's mind had been an important factor in limiting the life expectancy of many a risk which had been passed by the examiner in the past as first class. The author then proceeded to consider the methods by which the physician could determine its presence either in its incipiency or after it had progressed to a well-marked stage. He considered the etiology, symptoms and diagnosis. He said that Dr. Carl Beck relied on the X-rays in detecting a sclerotic condition of the arteries and determining whether it was local or diffuse. Neusser called attention to marked gastro-intestinal symptoms and to the abdominal variety of angina pectoris with burning pain deep in the epigastrium radiating over the thorax. In a recent article, Stengel called attention to the occurrence of an increased blood pressure as one of the earliest signs of this disease. He pictured cases of pseudoanemia with high arterial tension, and urine of alternately high and low specific gravity, and containing a number of cylindroids, as well as an increase in the total amount of urine. Suker and other oculists had emphasized the examination of the eyes in these cases, by which an early diagnosis could be made from the retinal changes, there being a thickening of the retinal arteries, and a compression of the veins where they were crossed by the arteries. Suker says: "The eye is the only place where one can get a direct view of the blood vessels; and hence an ophthalmologic examination should early be resorted to in all suspected cases." Stengel, in the article above referred to, says "When the heart is especially affected, symptoms may be in evidence early. Arrhythmia, increased force of the apex impulse, and suggestions of dyspnea are the most important of these." With the examiner bearing these points of diagnosis in mind, a suspicion of arteriosclerosis should be awakened early, and if the symptoms are not sufficiently pronounced to warrant a rejection, the interests of the company may be conserved, and no injustice done the applicant, by postponing him for further observation.

The Nerve Hygiene of School Children.—In a paper on this subject, Dr. Walter M. Fitch said that one of the most serious health problems now before the profession is the one of the enormous increase of insanity and neurasthenia. In view of this fact, the study of the development of the nervous mechanism and of the various phases of strain and stress put on it during growth becomes of paramount importance. The education of the modern child is of necessity a forcing process. The child must be prepared in early life for some form of industrial career. If not well prepared, for early industrial achievement, his success in life is more than doubtful. There is great importance in the method of teaching, but the strain of continuous nervous effort through the period of development profoundly influences the health of the nervous system throughout life. The medical guardians of the growing child are often careless in their watch on his health. Not only is his work in school allowed to be pushed to the verge of exhaustion, but unwise parents are permitted to add to this work an extra strain in the form of music study. The effect of this is the development of a predisposition to nervous breakdown. A second fault in medical practice recorded against the profession is that physicians often fail to remove bodily causes of peripheral nerve irritation. These irritations are usually slight, but become wearing and exhausting to the nervous system because of their persistency. The chief sources of peripheral irritation are phimosis, eye-strain, and the ovarian irritation of puberty in girls. The third fault in medical practice is the common neglect of the condition of subnormal respiration. This may be due either to obstruction in the respiratory passages, as from adenoids, or to weakness of the muscles of respiration, or to both causes; but suboxidation of the blood produces a condition of nerve poisoning which

greatly interferes with the normal development of the neurons. Broadly speaking, a broken or exhausted nervous system can never be restored to the normal, whether the derangement be structural or nutritional. One must look for the solution of this problem to hygienic measures adapted to the needs of the organism during its growth. One may prevent where he cannot cure.

GENERAL.

Antidote for Snake Bite.—It was announced at the annual banquet of the Association of American Physicians in Washington, on May 10, that as the result of researches by Dr. Noguchi, of Japan, working under a grant from the Carnegie Institution, a positive antidote for rattlesnake venom had been discovered. The announcement was made by Dr. S. Weir Mitchell, of Philadelphia, who read a letter from Dr. Noguchi, who is now at the Serum Institution in Copenhagen, where he has been making his researches for the past several months. From the nature of the announcement it is believed by the physicians who were present that the serum which Dr. Noguchi says he has discovered will prove to be of great value in human therapeutics. The fact that the announcement of the discovery was made by Dr. Mitchell is of particular interest, as more than forty years ago the latter worked long and unsuccessfully on the problem that has been solved by Dr. Noguchi. In his experiments he found that guinea-pigs that had received injections of rattlesnake poison up to twelve times the amount necessary to produce death and had then received injections of the anticrotalic serum experienced no evil effects from the poison. Dr. Noguchi also believes that this discovery will lead shortly to the discovery of serums for other poisons, and that it will not be long before the serums will be placed on the market, particularly in regions where the rattlesnake is always a factor to be reckoned with.

Money Where it Will Do the Most Good.—The Johns Hopkins Hospital has received its promised gift of $500,000 from John D. Rockefeller. The gift consists of $290,000 in cash and $210,000 in three classes of gilt-edged securities. Mr. Rockefeller surprised the trustees by sending an additional $1,600. This, in accordance with Mr. Rockefeller's business ideas, represents the interest on the gift from April 4, the day he announced it. With a list of the securities was sent a voucher for them to be signed and a brief note from Mr. Rockefeller, through his agent, saying he had made good his promise and expressing the hope that "it will do good to your most excellent institution." The securities will be retained and the money will be used to rebuild on the lots owned by the hospital in the burned district. Some of the lots will be sold and on others the hospital will now rebuild as rapidly as possible. The money received from Rockefeller represents about the hospital's loss by the recent fire.

Funds for the Hartford Hospital.—Probably one of the largest benefit performances ever given in the country was that for the Hartford Hospital on May 9 in Hartford, Conn., when more than $25,000 was realized and will be turned into the funds of the hospital. The performance was given by professionals headed by Marshall P. Wilder, who went to school in that city. The performance was attended by an immense crowd at Poli's Theatre, and was made one of the social events of the season.

Suits for Typhoid Damage.—An association has been formed in Butler, Pa., to bring actions for damages against the water company, the damage having been caused by the typhoid epidemic which lately ravaged that town, and the allegation of the complainants being that it was the result of negligence on the part of the water company in failing to protect the sources of its water supply and to maintain the purity and potability of the water it distributed. This is extremely interesting, and as the procedure is a new one the results of which can scarcely be forecast, it will be followed with attention.

Yellow Fever and the Mexican Frontier.—One case of yellow fever was discovered by the health authorities at Vera Cruz on May 9. The patient was sent to San Sebastian Hospital, and measures taken to prevent a spread of the disease. This is the first case for several weeks. The authorities are doing excellent work in house to house disinfection. On April 10 Dr. George R. Tabor, Texas State Health officer, received a telegram from Dr. Eduardo Liceaga, President of the Superior Board of Health of Mexico, saying that he would permit this State to send quarantine agents to that country. This is the concession Texas has been fighting for.

Stanley's Observations on Malaria.—The recent death of the African explorer, Sir Henry M. Stanley, brings to mind some curious observations made by him during his trip across that continent for the relief of Emin Pasha, and published in his work entitled "In Darkest Africa," 1890. Stanley found that the members of his party were attacked by malaria at all altitudes from 0 to 5,000 feet, and rather more frequently in the open country than in the jungles. It was his impression that symptoms of the fever were more prevalent while descending streams in boats than when ascending the same and that the direction of the wind had some influence. The most noteworthy remark was that of Emin Pasha himself, who, in early life, had received a medical training, quoting Stanley's own words: "Emin Pasha informed me that he always took a mosquito curtain with him, as he believed that it was an excellent protector against miasmatic exhalations of the night."

Hospital Appointments.—The following men have won appointments at St. Joseph's Hospital, Baltimore, for one year: Dr. H. C. Coburn, Jr., Columbian University, '03; Dr. Walton H. Hopkins, University of Maryland, '04; Dr. J. M. Lynch, University of Maryland, '04; Dr. C. T. Ralls, Physicians and Surgeons, Baltimore '04; Dr. Jos. J. Boucher, Physician and Surgeons, Baltimore '04.

OBITUARY.

Dr. Clinton Cushing, a well-known surgeon and gynecologist, died in Washington May 10. He had a wide reputation on the Pacific Coast, was a member of the faculty of the University of California, and maintained a private sanitarium in that State. Of late years he had retired from active practice and spent the winters in Washington.

Dr. Orissa W. Gould, well known for her philanthropy and missionary work, especially among the poor of the East Side, died on May 3 of cerebrospinal fever at the New York Hospital. On Sunday evening she was stricken at the Women's Missionary Society, 162 Second avenue, this city. She was removed to the hospital, where she died. Dr. Gould was forty-three years old. She began the study of medicine at an early age, and was graduated from the Women's Medical College of New York.

Dr. William H. McGee, a leading physician of Warren County, N. J., died at his home in Belvidere last Wednesday, aged fifty-six years. He was a member of the Warren County Medical Society and resident physician of the Pennsylvania Railroad Company.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Nineteenth Annual Meeting, held at Washington, D. C., May 10 and 11, 1904.

FIRST DAY—MAY 10TH.

Presidential Address.—The session was opened by the President's address delivered by Dr. Wm. T. Councilman, of Boston.

Increase of Membership.—Dr. Councilman said that an increase of membership seemed desirable, yet there were certain difficulties. Too great a number would take away the helpfulness of the Association, because pathologists and laboratory workers would not be brought in that intimate contact with clinicians which now constitutes the most beneficial and characteristic feature of the Association. Even with the present limitation of membership it seemed possible to admit certain of the young active workers whose presence would be eminently desirable.

Honorary Membership and Retirement.—Dr. Councilman suggested that after twenty years of active membership most men had ceased to be actively productive of new observations, so he suggested that each year those who have been twenty years members be placed on the roll of honorary members, with all their old privileges of discussion and presentation of cases, but their places on the active list to be taken by younger men. This would, after two years, the Association having been founded in 1886, give places for an average of seven new members each for many years. In this way the activity of the Association can be maintained and its usefulness to medicine in America not allowed to wane. As it is, the amount of good that has been accomplished by the Association since 1886 can scarcely be overestimated. It has been a great factor in the wonderful progress that has come in American medicine in these latter years.

Increased Dues.—The treasurer then announced that owing to the occurrence of a deficit the annual fee for next year would be $15 instead of the usual $10.

Reed Memorial Committee.—Dr. Janeway, of New York, and Dr. Wm. H. Welch, of Baltimore, seconded the nomination of a committee to cooperate with the trustees of the fund for the erection of a suitable memorial to Dr. Walter Reed, the yellow fever expert. Dr. Welch said that the movement is now well under way and though the character of the memorial has not been decided upon, much was being done to secure interest in it generally in the medical profession of the country.

Influence of Extract of Suprarenal Glands.—The first scientific business was the reading of a paper by Dr. S. J. Meltzer, of New York City, on the influence of extract of suprarenal glands on elimination and absorption, which he illustrated by specimens of tissues and exudates. In frogs if enough strychnine be injected so that ordinarily the animal would suffer from tetanus the simultaneous injection of adrenalin will either materially delay the occurrence of the tetanic phenomena or will prevent it entirely. This does not seem to be due to the neutralizing chemical action of adrenalin upon the strychnine but upon some biological action. If adrenalin be given to frogs a condition resembling paralysis supervenes. The animal does not move and even when placed on its back, does not right itself. This paralyzing action seems to neutralize the effect of the strychnine. In rabbits the injection of enough strychnine normally to cause fatal tetanization, if followed by adrenalin injections, will have no effect, or the effect will be delayed for hours. These observations seem to point to delay of absorption.

Fluorescence Experiments.—Fluorescein causes coloring of animal tissues—the cornea, the mucous membranes, etc., without hurting the animal. If adrenalin be injected just before the injection of fluorescein the coloring of the tissues is much slower and even less complete. With regard to elimination of the fluorescein through the kidneys there is distinct evidence of delay. On the other hand, the substance is deposited much more slowly in such internal tissues as the liver and the kidneys and more of it is found to be retained in the blood serum.

Practical Applications.—Dr. Meltzer suggested that adrenalin might be employed with advantage to delay the elimination of certain drugs, the retention of which in the organism is too brief to accomplish the purpose expected of them. On the other hand, the danger of delay of elimination of toxic substances, as during nephritis, might be dangerous and when toxemic conditions are present adrenalin will have to be used with more care than is now the rule.

Therapeutic Administration.—Dr. W. Gilman Thompson, of New York, said that in cases of typhoid fever particularly, where he administered adrenalin for hemorrhage, he had never seen any effect produced by the substance either on the amount or the character of the urinary secretion. It seems unlikely then that in ordinary therapeutic doses it can have the danger that Dr. Meltzer suggests.

Brief Action of Adrenalin.—Dr. Hobart A. Hare, of Philadelphia, said that seeing the very brief action of adrenalin it seems utterly unlikely that any serious delay of elimination can be brought about or that the action of drugs over a longer time than normal can be secured by means of it, unless it be administered more frequently than is now the case. Dr. Hare has, however, seen adrenalin produce apparently greater susceptibility to infection. In tonsillitis, for instance, when used in a spray to decrease congestion and lessen pain the surface covered by exudate is apt to be increased in some cases and certain of the cervical glands, even of the deep chain, may become affected. Whether it may not have a like effect upon the nose must be borne in mind. When used hypodermically, though with all the precautions that usually save the patient this inconvenience, the occurrence of sloughs is by no means unusual and seems to be due to the loss of tissue resistance under the action of adrenalin.

Duration of Action.—Dr. Meltzer, in closing the discussion, said that the length of the action of suprarenal is as yet unknown. On striate muscle fiber it seems to act for a very brief period; on unstriated fiber for a longer period. On the endothelium of capillaries, which is of contractile nature, its action seems to be prolonged. The action time of the substance is now actually being studied and was really one of the problems looked into in the present investigation. The practical applications suggested are only meant to call the attention of medical men to certain lines of thought.

Polyuria in Typhoid Fever.—Dr. M. Howard Fussell, of Philadelphia, reported a case of typhoid fever in which polyuria, to a very marked degree, set in about the tenth day. On the twelfth day the patient passed 7 quarts of urine; on the fourteenth day 15 pints and more than 3 quarts every day afterward, until the temperature became normal. There were no abnormalities of the urine and the normal quantity of urea was passed. The patient had no history of ever having had polyuria before and has had none since. There were very severe functional nervous symptoms amounting practically to attacks of hysteria during the polyuria. The patient was very restless, being compelled to pass 6 ounces of urine every hour or so and the skin became dry. Polydipsia followed the increase of urination but did not precede it. The patient had taken salol, but this, later,

when in health, showed no tendency to increase his urine. Analysis of other cases shows Dr. Fussell that polyuria in the convalescence from typhoid fever is not as common as would be believed from the statements in text-books.

Retention of Water in Fevers.—Dr. George Dock, of Ann Arbor, Michigan, said that the old theory that water is retained in fevers, that is, that febrile patients have a notable disproportion between the amount of urine passed and the liquid consumed, would seem to need investigation. Certain it is that the use of the bath has materially increased the amount of urine, as a rule, and that this has something to do with its good effect. Cantani tried to treat patients by large amounts of fluids and found that when 14 quarts of liquid were given about 12 quarts passed off in the urine. The specific gravity in cases of polyuria thus induced is not very far from normal, in Dr. Dock's experience, and there is not the thin, light-colored urine that might be expected.

Polyuria and Abdominal Pain.—Dr. Osler, of Baltimore, said that many painful conditions of the abdomen are associated with polyuria and this may be held to account, in some measure at least, for the polyuria of typhoid in its latter stage. Individual patients are very variable in this respect, however. Aneurism of the abdominal aorta is very frequently associated with polyuria. Other tumors may have a like effect, especially in neurotic individuals in whom, for some not well understood reason, the tendency to variability of the urinary flow is quite marked.

Copious Water in Typhoid Fever.—Dr. Wm. S. Thayer, of Baltimore, said that in Cleveland Dr. Cushing has been treating typhoid fever cases with all the water they want. Of late years there has been a well-marked determination to give typhoid patients frequent drinks, yet they never seem to be satisfied. Dr. Cushing has a small reservoir of fresh water placed beside the patient's bed and from it a tube, through which, without disturbing himself or others, the patient may suck water whenever he wishes. In this way enormous quantities of water are consumed, sometimes several gallons a day. There is a corresponding increase in the amount of urine passed. One patient passed nearly 500 ounces in twenty-four hours. The result of this treatment has been very favorable. Patients are less restless and the mortality is lower. The idea of washing out intestines and the blood of toxic material seems to be thus accomplished to the satisfaction of patient and physician.

Dr. Fussell, in closing the discussion, said that the polyuria seemed to precede and be the immediate cause of whatever polydipsia was present in the case.

Venous Thrombosis in Typhoid Fever.—Dr. Wm. S. Thayer, of Johns Hopkins Hospital, analyzed the 39 cases of thrombosis in typhoid fever which have occurred at that hospital. Five were fatal, two of them through embolism of the lung. Twenty-six of the cases occurred on the left side, 5 on the right, 9 on both sides. In 21 cases the femoral vein was affected, in 5 the popliteal, in 5 the iliac and in 5 the veins of the calf. One occurred during the first week, two during the second, some scattering cases up to the thirteenth week but most cases in the fourth, fifth and sixth weeks and after the fever had subsided.

Symptoms and Course.—In all but one of the cases of femoral vein thrombosis there was pain along that vein and in 9 cases there was also pain in Scarpa's triangle. The symptoms always began with striking suddenness though usually before the localized pain there was a general malaise with chill. Some of the chills were very severe. In the case of iliac thrombosis there was sharp abdominal pain with signs of shock, causing the suspicion of perforation. Exploratory laparotomy was done and the true condition ascertained. The patient recovered without complication. Leucocytosis was present in all the cases, in most being over 10,000 white blood cells to the cubic millimeter. Some inflammatory changes in the walls of the veins were found in cases where autopsies were made but it was not decided whether these were not secondary rather than primary. The accepted idea of etiology is the occurrence of phlebitis as a predisposing factor to the thrombosis.

Permanent Disability.—All of the patients under observation at Johns Hopkins have more or less permanent disability as the result of the thrombosis. The leg is distinctly weaker, it is permanently enlarged and feels cumbrously heavy and on much exertion it swells and compels the patient to rest. The acme of discomfort is noticed in the summer time, though some patients complain of cold feet in the winter and of the tendency for the affected limb to go to sleep. Whatever of relief has come in most cases has been the result of the formation of a collateral venous circulation by means of varicose dilatation of veins. In most of the cases the varicose veins are to be seen not only on the leg but also in a triangle on the abdomen the apex of which is the umbilicus and the blood is evidently thus passed to the other side. In cases of iliac thromboses the varicose veins run up above the umbilicus, making anastomoses with the internal mammary veins, also with the axillary. These veins are large tortuous structures and give the usual discomfort of varicose veins for other reasons.

Calcium Salts and Thrombosis.—Dr. Geo. L. Peabody, of New York, said, in opening the discussion, that experiments seem to show that the presence of abnormally large amounts of calcium salts in the blood predispose to the formation of thrombi. The increase of calcium salts is easy to understand in the blood of typhoid fever patients fed exclusively on milk, for milk contains a large proportion of calcium salts. To neutralize the tendency for these to cause blood coagulation the ingestion of citric acid or soluble citrates in considerable quantities has been suggested as a routine practice. As most patients with typhoid fever rather like lemonade, it is not a difficult matter to carry this out.

Preliminary Fever.—Dr. Alfred Stengel, of Philadelphia, said that a set of general symptoms has in his experience nearly always preceded the occurrence of thrombosis. This would seem to show the presence of an infectious focus from which some absorption was taking place and apparently points to the existence of a previous phlebitis. Some of the chills were very severe and there was high fever with a sweat—the whole process partaking of the septic type.

Dr. Wm. H. Welch said that the tendency now is to revert to the old explanation of a preceding localized phlebitis as the cause of the thrombus formation. For a long period Virchow's studies were supposed to have disproved this but the French school have upheld it and have shown of late years that there are excellent reasons for it. One feature that favors it is the occurrence of general symptoms before the local thrombosis shows itself. Especially is there apt to be a marked disturbance of the pulse with the development of a period of extraordinary rapidity, out of all proportion to the temperature at the time, though that may be notably elevated.

No Complete Recovery.—Dr. W. Gilman Thompson, of New York, said that he has never seen anything like complete recovery of the usefulness of the limb after thrombosis. Large varicosities do help the circulation but prove a source of discomfort in themselves. In a recent case in whom, after iliac thrombosis, large abdominal veins had formed, the patient developed appendicitis and the incision had to be carefully planned so as to avoid these vessels, some of them larger than the little finger.

Dr. James Tyson, of Philadelphia, said that in all cases of vascular obstruction pain is a prominent symptom. In angina pectoris in the obstruction of the artery of a leg preceding gangrene even in the ordinary cramps it seems not unlikely that the underlying cause of pain is the constriction of arteries. The subject deserves to be investigated from that aspect.

Disability not Permanent in Many Cases.—Dr. Wm. Osler, of Baltimore, said that in many cases the disability is not so permanent, nor so serious as is said. He has seen cases which recovered completely. In fact, he considers that all who have healthy vascular systems will recover completely. To his students he says, always blame the parents for not having given the patient a good venous system when the prognosis of ultimate recovery does not seem likely to be fulfilled. Venous thrombosis after typhoid is very different to the form known as phlegmasia alba dolens after puerperal fever. Very rarely if ever does the limb become swollen as in this, or so white or tender to the touch. The phlebitis is of mild character and is not extensive.

Clinical Studies in Arteriosclerosis.—Dr. Alfred Stengel, of Philadelphia, said that in spite of the general impression to that effect blood pressure in arteriosclerosis is not necessarily always high. His measurements were made with the Riva-Rocci instrument for determining blood pressure as modified by Stanton. This measures not only systolic but also diastolic blood pressure. Diastolic blood pressure is always high in these cases until the myocardium gives out, when of course, there is a fall. Dr. Stengel's results were confirmed by a manometer applied to a peripheral artery. Sustained diastolic pressure is a very early manifestation of arteriosclerosis. Dr. Stengel also noted the excellent condition of the blood in some patients in whom the rapid development of arteriosclerosis with its characteristic pallor had brought the thought of malignant disease. In these cases the hemoglobin was 80 to 90 and the red blood cells not below 4,000,000. This seems to show that very small arteries, perhaps even the capillaries themselves, are early involved in the arteriosclerotic process. This is of course an interesting problem for which solutions have so far been vainly sought.

Urine in Arteriosclerosis.—The urine in arteriosclerosis in Dr. Stengel's experience shows a very decided tendency to vary greatly from time to time. The specific gravity of the morning urine may be 1.015, that of the evening 1.030 to 1.035. This variability is common, also to the amount of urine passed, even in cases where the absence of any formed elements that are distinctly pathological, shows that the kidneys themselves are very much affected in their secreting substance.

Earliest Sign of Arteriosclerosis.—This, in Dr. Stengel's observations, is always a prolongation or sustaining of the first heart sound. Long before there is an accentuated second sound this sustaining of the first sound will be quite audible.

Dr. Solomon Solis-Cohen, of Philadelphia, said, in the discussion, that a prolongation of the first sound of the heart without any distinct murmur is very common in the early stages of arteriosclerosis. With regard to diastolic tension Broadbent long ago called attention to the fact that very early in arteriosclerotic conditions there was a sustenance of the tension of the pulse between beats. This is evidently the same sign as is now described as high diastolic tension. In the urine of arteriosclerosis Dr. Cohen has noted a diminution of the toxic elements evidently due to the fact that the arterial change prevented so much blood from going to the kidneys and also interfered with the secreting mechanism.

Strychnine in Fever.—Dr. Richard Cabot, of Boston, gave the details of a number of observations in febrile conditions, mostly typhoid fever, some pneumonias and other fever conditions in which strychnine was administered. The blood pressure of these patients was measured with Stanton's modification of the Riva Rocci sphygmomanometer. In none was there any rise of blood pressure following the administration of strychnine, though all the patients received 1/8 grain per twenty-four hours and some of them as high as 1/6 grain. When the strychnine was abruptly stopped no effect either on blood pressure or on their general condition was noted. At times it was noted that the visit of a friend or the coming of the meal tray had a decided effect on blood pressure such as could not be obtained with even large doses of strychnine.

Strychnine not a Cardiac Stimulant.—Dr. Hobart Amory Hare, of Philadelphia, said that though used as such by most of the members of the medical profession strychnine is not a direct heart tonic. It acts by irritating the nervous system and is something like applying a whip to a high-strung horse already putting forth every effort but overloaded. Whatever beneficial action there is from strychnine is due to the equalization of the circulation. If Dr. Cabot's experiments then will have the effect of making many people revise their conviction as to the action of strychnine much will have been done, even though his observations have all been negative.

Beginning of Nephritis.—Dr. Wm. H. Thomson, of New York, said that there is evidently some substance which causes the high blood pressure so often to be observed before the beginning of true nephritis. Apparently it is the action of this substance on the kidney tissues that eventually leads to their degeneration. The action of this toxic substance resembles very much that of suprarenal extract. Only very minute amounts of the substance are required to produce high blood pressure through narrowing of the arteries, probably not more than 1/500 of a grain being required. Dr. Thomson suggests that the beginning of nephritis may be due to some disturbance of suprarenal function. The tendency of suprarenal extract to produce contraction of kidney tissue has often been shown and would serve to demonstrate how contracted kidney comes about. Dr. Thomson's conclusions with some suggestions as to the practical value of the idea in therapeutics he summarized as follows: (1) High tension pulse occurs too early in nephritis to be due to any other cause than the presence in the blood of a general vasoconstricting agent, similar in its properties to adrenalin. (2) Such an agent would also produce constriction of the renal vessels and general shrinkage of the kidneys, causing interference with the excretion of urea. (3) Prolonged presence of such an agent in the blood would lead ultimately to endarteritis with degeneration of the vascular walls and to cardiac changes. (4) Acute cardiac dilatation may occur from the effects of such a general vasoconstricting agent in the circulation before extensive alterations in the blood vessels have taken place. (5) Aconite is the best vasodilator in nephritis, much more effective than the nitrites. Marked increase in the excretion of urea follow its administration in cases of high tension and Dr. Thomson has used it with excellent results.

Illuminating Gas Poisoning.—Dr. W. Gilman Thompson, of New York, analyzed some 90 cases of poisoning due to illuminating gas inhaled accidentally or with suicidal intent. There were 288 fatal cases in New York in 1902, due mainly to the gas stove and its rubber connections and also to the fact that many persons with no knowledge of gas find their way to New York City. The most prominent feature is the change of the hemoglobin into methemoglobin which prevents the red blood corpuscles from any longer fulfilling their rôle as oxygen carriers. Another almost constant blood change is a large leucocytosis. All the fatal cases had

more than 18,000 white cells, the increase affecting especially the polymorphonuclear cells. Some of the cases showed as high as 50,000. One recovery occurred where the leucocytosis had risen to 44,000.

Clinical Symptoms.—All severe cases show coma, but neither the depth nor length of the coma furnishes any positive indication of the prognosis of the case. After a time all of the cases develop fever usually about 103° F. Some very interesting fatal cases show hyperpyrexia, one as high as 110° F. There is always a marked fall in the respiration rate which may go as low as 3 or 4 to the minute. This appears, however, to be of central origin and pneumonias following the inhalation of gas is rather infrequent. Once the patients begin to recover, convalescence is rather rapid, but at times complete recovery is long delayed, and not always can an adequate reason be found for the prolonged prostration.

Nervous Symptoms Most Important.—The nervous symptoms and their underlying lesions are the most prominent features of illuminating gas poisoning. They are apparently due to the carbon monoxide in the gas. The lesions in the fatal cases are found to be softening and edema of the brain, small hemorrhages from the rupture of minute arteries. These latter phenomena are indeed the specific lesions of gas poisoning. In about 7 per cent. of all cases convulsions develop. Some paralysis hemiplegia or hemiparesis is not uncommon. It is often marked by the patient's comatose condition. There is often a softening of the lenticular nucleus.

Dr. S. Weir Mitchell, of Philadelphia, said that illuminating gas was so different in different cities, or even in different parts of the same city, that the clinical pictures presented in cases would necessarily have many features not in common with one another. Until more was known of the definite composition of such gas, it seems idle almost to discuss the symptom complexes and lesions which it produces.

Defibrinated Blood.—Dr. Stengel said with reference to treatment by intravenous injections that in experiments made upon animals in Philadelphia it seemed to be demonstrated that the use of normal saline injections did not avail to save life, though injections of defibrinated blood from the same animal did.

Dr. Kinnicutt, of New York, said it was very difficult to obtain defibrinated human blood always just when wanted and, besides, when it was obtained surgeons were not always able to inject it successfully.

Dr. W. Gilman Thompson, in closing the discussion, said that it was not always the presence of methemoglobin that killed the patient, for at times the blood was not saturated. This had been demonstrated by finding spectroscopic evidences of hemoglobin in certain cases. Besides, at times, there was recovery as regards the blood condition, yet the patients went on to a fatal termination because of their nervous conditions. Warm saline solution often does good in cases of poisoning by illuminating gas, and as it is so handy it should always be given a thorough trial.

Serum for Rattlesnake Bites.—Dr. S. Weir Mitchell, of Philadelphia, read a letter from Noguchi, the Japanese pathologist, who has been working at the University of Copenhagen, under a grant from the Carnegie Institution. After having studied the question of a serum for rattlesnake bites with Prof. Flexner, at the University of Pennsylvania with some encouraging results, he now announces that he has succeeded in preparing goat serum so that it will prove efficiently curative for rattlesnake bites. The serum is prepared by rendering the goat immune to the action of *Crotalus* poison by gradually increased doses.

Etiology of Exophthalmos.—Dr. MacCallum, of Johns Hopkins, discussed the various causes that have been assigned for the prominence of the eyeballs in exophthalmic goiter and showed that they were all insufficient. He then detailed observations which seemed to prove that exophthalmos is due to the contraction of a cone-shaped structure surrounding the eyeball and containing some unstriped muscle fibers. The contraction of this throws the eyeball forward. Dr. MacCallum's work was made possible by the construction of an instrument by means of which the slightest projection of the eye bulb can be measured and even the rhythmic projection of it, due to pulse and respiration, can be clearly demonstrated.

Diabetes Insipidus.—Dr. Thomas B. Futcher, of Baltimore, described and analyzed the series of cases of diabetes insipidus which have occurred at Johns Hopkins Hospital since its inception. Altogether they are only seven in number, six in the hospital and one in the dispensary. There have been over 7,000 patients in the hospital, so that diabetes insipidus is actually and comparatively a very rare disease. Out of these seven cases four had had syphilis and all of these improved in the administration of potassium iodide. The other causes seem to be heredity, which has been confirmed by the observation of a family for four generations among the ninety members of which more than one in five suffered from the disease. The tendency for the affection to be a sort of equivalent for tuberculosis in preceding generations seemed to be established. The affection occurs much more frequently in males than in females and is most frequent in the decade from thirty to forty years. Perhaps one reason for this is that it is just at this period that syphilitics are most likely to suffer from nervous symptoms due to cerebral lues. The cures effected by the use of potassium iodide are often very marvelous, and even in one case where syphilitic history was denied there was clearing up of most symptoms in a few weeks with a gain of nearly twenty pounds in weight.

Tuberculosis and Diabetes Insipidus.—Dr. Wm. H. Thomson, of New York, said that in one case under his observation a fatal termination showed at autopsy the existence of a miliary tuberculosis. As some of the tubercles were on the floor of the fourth ventricle, where Claude Bernard had found a center for diabetes insipidus just in front of that for diabetes mellitus, this seemed to be the pathological basis for the disease.

Potassium Iodide.—Dr. James Tyson, of Philadelphia, said that this drug often seems to do good even where syphilis is not present. A young fellow whom Dr. Tyson first saw at the age of twelve years is now, after ten years, completely rid of his diabetes insipidus, the main treatment employed being potassium iodide.

Dr. Dock, of Ann Arbor, Mich., said that the more suspicious the previous history as to syphilis the better the prognosis in these cases. In other cases apparently developing on a neurotic basis the outlook is not favorable.

Diabetes Insipidus Not Rare.—Dr. Abraham Jacobi, of New York, said that among children at least diabetes insipidus is by no means a rare disease. It occurs in connection with chorea and other convulsive incidents in child life. Occasionally it is seen after severe whooping cough in delicate children, when it is usually concluded to be due to minute cerebral hemorrhages resulting from the convulsive coughing. In boys from seven to twelve years it is not infrequent as the result of falls upon the occiput. Tumors of the brain cause it. Heredity plays a rôle in its etiology, not only directly but also by the transmission of nervous constitutions. It is often associated with hereditary syphilis. Potassium iodide is the most generally useful remedy in the disease, but in some cases where it fails ergot controls the condition, or at least diminishes the

amount of urine passed. It seems to be especially of use in the non-syphilitic cases.

Unsuspected Irritation of Internal Abdominal Ring.—Dr. Charles G. Stockton, of Buffalo, reported some twelve cases in which irritation at the internal abdominal ring in persons with a hernia and wearing an ill-fitting truss gave rise to peculiar discomfort, sometimes amounting to absolute pain, which led to the diagnosis of other serious abdominal conditions. Now, when so much attention is paid to intra-abdominal pain of any kind, this group of reflex cases is especially important. Since Dr. Stockton has come to recognize it the number of cases seen has increased and it seems clear that many more persons are suffering from it than might be expected. The treatment of the condition, which also at once serves to confirm the diagnosis is to apply a well-fitting truss.

Prolonged Hysteria.—Dr. S. Weir Mitchell reported a case of a severe type of hysteria which has been under his observation since 1876. The patient went through a number of varied movements as the result of his hysteria. One was the pendulum swing of his arm to and from the body some 150 times to the minute. Later a rotary movement of the same arm developed, the hand being carried round the shoulder over 100 times to the minute. Notwithstanding the apparently exhausting character of these movements persistently carried on during his waking hours, the patient did not seem to suffer from fatigue and remained in excellent health. If the movement was stopped the patient suffered intensely and there was a tendency at least often completed to the development of a generalized convulsive movement. All ordinary drug treatment failed and the patient visited many clinics and physicians. Finally hypnotism was tried but the patient had a decided objection to it. Some 30 seances were held but he was never brought so completely under its influence as to lose sense perception. After a time, however, his convulsive movements became less and then disappeared completely, so that for some three months he was able to take a position as assistant librarian at Jefferson Medical College, Philadelphia. At the end of that time, however, there was some difficulty causing emotional strain and the old-time convulsive movements reappeared. This time he absolutely refused to be treated by hypnotism, saying that since the Lord had visited him with the affliction he must needs bear it. After a time Dr. Weir Mitchell himself succeeded in persuading him to submit to hypnotism again and he was somewhat improved, but he seemed to be less comfortable generally when the movements were not going on. Perhaps he lacked the attention which, because of his very peculiarly interesting condition, was showered upon him. His death took place suddenly and without any apparent cause.

Autopsy Findings.—The autopsy was made very carefully and with minute completeness by Dr. Spiller, who found absolutely nothing that could be considered pathological. It seems difficult to Dr. Mitchell to understand how these rapid movements could continue for so long without being registered on the cerebral cells. Of course the arm area of the side opposite the convulsed arm was minutely examined. The case is ideal as a document in hysteria. No other pathological condition had supervened to spoil any characteristic changes of hysteria that might be present and yet absolutely nothing even suspicious was found. This is not so surprising, however, when it is realized that there are so far as known no specific pathologic lesions for chorea or the convulsive tics or paramyeclonus multiplex and related syndromes described of late years.

Observations on Subliminal Consciousness.—Dr. Morton Prince, of Boston, gave some details of recent observations on a young man suffering from hysterical manifestations including anesthesia and paresis. While he could not feel he yet could be made to see reflected in the surface of a glass of water in which he was told to look, a hand on which he could count the number of times he was touched. His first attack occurred after a fright one night when he was passing a cemetery on a lonely road. Whenever in hypnosis he could be made to go back in his history beyond that night he did not suffer from the anesthesia and other accidents which had developed at that time, so that there seems to be a record in the brain of successive states of consciousness and the later conditions may rule the external sensibility.

Dr. Horatio C. Wood, of Philadelphia, said that the absence of a record on the cerebral cells of movements accomplished is not surprising. It is the voluntary control of cells that would seem to register itself while the cells are protected from interference with their normal functions by their lower connections in the nervous system. Chorea and convulsive movements generally seem to be the assumption by voluntary muscle of the character of such involuntary muscles as the heart and the unstriped muscles generally which execute rhythmic movements.

Unusual Forms of Acute Myelitis.—Dr. B. Sachs, of New York, reported some anomalous cases of acute myelitis which seem to throw light on the recent discussions with regard to forms of infectious myelitis and cases where no infection can be traced, yet without syphilis or trauma in the history. In one of his cases the symptoms that developed were evidently of the nature of a spinal apoplexy due to the rupture of a blood vessel in the cord in a person suffering from degeneration of arteries. The existence of such changes cannot be doubted and the arteries of the cord may rupture as well as the brain. Such cases are undoubtedly rare, yet their possibility must ever be taken into account.

Streptococcic Myelitis.—In the case of a young girl the symptoms of myelitis developed just before the occurrence of a series of multiple abscesses in various parts of the body. The first of these abscesses in the inguinal region, was thought to be tuberculous and connected with the spine, which did not prove to be the case, however. In all the other abscesses streptococci were found practically in pure culture. It was concluded then that the focus in the cord was also of streptococcic origin. It was proposed to test this by lumbar puncture, but Dr. Sachs preferred not to, as there seemed to be danger by lessening the pressure within the spinal canal of generalizing the streptococcic process. The most interesting feature of the case is that the girl's life was not only preserved but there was some return of function in the leg movement, which had been lost. The severity of the symptoms, together with the inevitable diagnosis of its streptococcic etiology, seemed to justify the most unfavorable prognosis.

Spinal Ischemia.—Dr. Wm. H. Welch, of Baltimore, said in discussing Dr. Sachs' paper that sometimes there seemed to occur a contraction of the arteries supplying special segments of the cord producing a true ischemia and that such an incident led to softening, if there was persistence of the condition, and also to the development of a set of symptoms closely resembling those of transverse myelitis of infectious or other origin. The distribution of the spinal vascular system was for purposes of protection of the delicate nerve substance and such that this accident became possible under certain circumstances.

Infectious Neuritis and Myelitis.—Dr. James J. Putnam, of Boston, presented the details of some cases

of infectious myelitis which showed the insidious nature of this affection and its tendency to get well at times under conditions that would seem to justify the worst prognosis. The advance of paralysis upward was sometimes to such an extent that even respiration was ultimately interfered with. The paralysis is, however, more commonly confined to the legs.

Cerebrospinal Meningitis Epidemic in Children.—Dr. Henry Koplik, of New York, said that this subject is now of special interest, owing to the occurrence of various foci of the disease in many parts of the country. Certain symptoms that have been recently described are of value for the differential diagnosis, others are not. The Babinski toe reflex, for instance, is usually not present in epidemic cerebrospinal meningitis, while it is usually present in tuberculous meningitis, thus constituting a valuable aid to diagnosis. The Kernig sign is not of special significance. Papillitis is quite common in tuberculous meningitis and is very rarely seen in cerebrospinal fever. This supplies some of the most valuable differential criteria between the two diseases. The leucocyte count of cerebrospinal meningitis is invariably very high, on the average above 24,000, while in tuberculous meningitis it is present but is much lower. The height of the leucocyte count has no special significance for prognosis, however. The *Diplococcus intracellularis* of Weichselbaum is found to be present in most cases. A comparatively low leucocyte count is found in certain forms of the disease, in which at autopsy the lesions are confined to the occipital region. These cases have lately been separated from the others by Still and the symptom-complex he suggested seems justified by further investigation.

Treatment by Lumbar Puncture.—Dr. Koplik considers that lumbar puncture should be a routine treatment especially in very young children suffering from the disease. The evacuation of some cerebrospinal fluid always brings with it some relief of symptoms, such as coma, and in the interval of better feeling thus occasioned there is not infrequently established a direct tendency to cure. A better proportion of those treated by lumbar puncture recover than of those not so treated in Dr. Koplik's experience. His paper will appear in full in an early issue of the Medical News.

Spasmodic Stricture of Esophagus.—Dr. James Tyson, of Philadelphia, described a case of cardiospasm in which the patient, though not suffering from any gross pathological condition in the esophagus, find it extremely difficult to swallow. After food had been taken and apparently swallowed the patient felt a lump behind the lower end of the sternum. Unless this was relieved by forcing into the stomach the food would later be returned by regurgitation. The method of forcing consisted of drinking rapidly large quantities of fluid. On one occasion Dr. Tyson saw the effort required at the end of a meal. The patient drank in large gulps about eight ounces of hot tea, about eight ounces of cold milk and then, finally, about six ounces of cold water, after which by a supreme effort the food entered the stomach. Dilatation of the cardiac end of the esophagus by means of an instrument resembling certain urethral dilators was attempted and with some success. The instrument was passed into the stomach, closed and then drawn out open. The patient complained of great discomfort associated with these manipulations, however, and refused to have it repeated. The spasm recurred and gastrostomy was performed.

Cardiospasm, Idiopathic; Dilatation of the Esophagus.—Dr. B. W. Sippy, of Chicago, presented the specimens from a case of cardiospasm, showing great dilatation of the esophagus so that instead of 100 c.c., as is normal, it held 500 c.c. of fluid. Just about the cardiac orifice the fibers, circular and longitudinal, of the esophagus had become hypertrophied to at least six times their normal thickness. There was no stricture of the esophagus at any point and apparently no cause for the cardiospasm and dilatation. The patient was a physician's wife and the condition at first was thought to be pyloric stenosis with vomiting. No narrowing of the pylorus could be found. The presence of the destructive condition in the esophagus was detected by Dr. Sippy *intra vitam* but the patient was too far gone to be improved. The X-ray picture of the esophagus with the use of bismuth had especially aided in the diagnosis of esophageal dilatation.

Record Esophageal Dilatation.—Dr. Francis Kinnicutt, of New York, then presented the specimens from a case of dilatation of the esophagus which are the largest on record. The esophagus held 1,800 c.c. of fluid, eighteen times the normal amount. There was in this case also a dilatation of the stomach. No adequate cause could be found for either, though the presence of some narrowing of the pylorus might account for the gastric condition.

At the banquet a series of lantern slide illustrations of certain recently described parasitic protozoa were exhibited.

Protozoa of Scarlet Fever.—Dr. F. A. Mallory, of Boston, demonstrated the appearances in the skin in early stages of scarlet fever which he has recently described and which seem to be evidence of the presence of protozoa, the probable cause of the disease. The most striking of these appearances is a rosette-shaped body not unlike a similar appearance seen in the life cycle of the malaria parasite just before the *Hematozoon malariæ* of Laveran breaks up into the smaller bodies that constitute the second generation of the malarial parasite. The appearances seen in scarlet fever are best observed on the second day of the cutaneous rash. They usually occur within the epithelial cells but have been observed also in the lymph spaces in the corium. These observations seem to demonstrate that the appearances are not those of degeneration in the epithelium, since they occur also outside of the cells. The rosette form of the scarlet fever protozoon is about one-third larger than the malarial parasite of the tertian variety.

Proof Not Degeneration Phenomena.—Some of the slides show the parasite also within epithelial cells in which mitotic figures are to be seen. This indicates an active healthy division stage of the cell and would seem to preclude all idea of degeneration being the cause of the appearances degeneration and multiplication by mitosis being incompatible in the same cell. Besides the parasite does not take the stain of degenerative material, but the vivid coloring of living material. Certain of the stages of the parasite are very small and apparently have ameboid movements.

Trypanosomiasis Multiplex.—Dr. Frederick G. Novy, of Ann Arbor, Mich., then demonstrated the various forms of trypanosomes. For a time it was thought that there was only one type of trypanosome, but recent investigations have shown that there are many, some pathogenic for one animal, some for another. The surra of the Philippines and of South Africa are two distinct diseases. There is besides a South American trypanosome. In this country certain rats are affected by a special trypanosome which is not pathogenic for rabbits. Dr. Novy showed the special peculiarities of the various trypanosomes, some larger and slender with a large undulating membrane, some shorter and thicker, with flagellate terminations. A knob-like termination to the flagella characteristic of one form that does not occur in others. While belonging to the same family

with many appearances in common and a similar method of division there are separate forms requiring special study.

Chloroma and Eosinophilia.—Dr. George Dock, of Ann Arbor, Mich., exhibited some slides from the blood and various tissues of a case of chloroma in which many large eosinophiles, filled with characteristic granulations, were to be seen. Some of these cells showed degenerative areas with vacuoles and very irregular grouping of the granular material. Large lymphocytes with but a narrow area of protoplasm were also present, some of them of small size seemed to be incompletely developed, many of the large eosinophiles seem to be myelocytes; that is, cells of bone-marrow origin, and are apparently the result of a natural but unsuccessful reaction to some irritant in the circulation.

Second Day—May 11th.

New Members.—The following nominees recommended by the Council for membership were elected: Philip King Brown, of San Francisco; Joseph Collins, of New York; David L. Edsall, of Philadelphia; Frederick Gault Finley, of Montreal; Hermon C. Gordinier, of Troy, N. Y.; Richard M. Pearce, of Albany, N. Y.; Mark W. Richardson, of Boston; Richard P. Strong, of the U. S. Army .

The following were elected as honorary members: Beverly Robinson, of New York; Starling Loving, of Columbus, Ohio; Henry G. Walcott, of Boston, Mass.

The following nominations for office, made by the Councillors were accepted and the officers for the next year are, for President, Edward L. Trudeau, of Saranac, N. Y.; Vice-President, Frank Billings, of Chicago, Ill.; Secretary, Henry Hun, of Albany, N. Y.; Recorder, Solomon Solis-Cohen, of Philadelphia, Pa.; Treasurer, J. P. Crozer Griffith, of Philadelphia, Pa.; Councillor, F. Forchheimer, of Cincinnati, Ohio; Representative in the Executive Committee of the Congress of American Physicians and Surgeons, William Osler, of Baltimore, Md.; Alternate Representative, Francis H. Williams, of Boston, Mass.

(To be Continued.)

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held March 14, 1904.

The President, Thomas E. Satterthwaite, M.D., in the Chair.

Symposium on Dilatation of the Stomach, Gastroptosis, and the Methods of Physical Diagnosis.—This was opened by Dr. Robert Coleman Kemp, who said it had unfortunately been too often the habit to depend on the examination of the stomach contents alone, and to neglect the investigation of the motor functions and the position of the stomach itself. The latter is necessary in order to arrive at an accurate diagnosis, as well as give a correct prognosis and undertake proper treatment.

Atony of the Stomach.—This must necessarily first occur before dilatation of the stomach is produced. Atonia gastrica may be defined as a loss of tone or contractile power in the muscles of the stomach, so that the organ becomes distended and does not contract about its contents, with a resulting motor insufficiency. While the dilatation of the stomach in gastroptosis is disputed by some, his own observations have shown that dilatation does exist, and with it, necessarily, a varying degree of motor insufficiency.

Dilatation of the Stomach.—Boas has demonstrated that an apparently dilated stomach may really be in a condition of compensatory hypertrophy. It may, therefore, be stated that as long as the functions of the organ are normal, the condition met with cannot be regarded as pathological. In dilatation the lesser curvature maintains in general its relation to the diaphragm, and this is the differential point between dilatation and gastroptosis. A number of forms of acute dilatation have been described. The first is the result of acute inflammation of the gastric mucous membrane. It is uncertain whether it depends on pyloric spasm or paralysis of the gastric muscles, or on both these causes. The second is a postoperative dilatation, following abdominal section, especially. It would seem to be due to some shock of the sympathetic system, either from the operation or the anesthetic, or possibly, later, from uremia or sepsis. Among the other types of acute dilatation mentioned are the following: In typhoid fever; during attacks of migraine and just preceding epileptic seizures in certain instances; during the course of pneumonia and other pulmonary diseases; in convulsions in infants and young children from overloading the stomach; in attacks of pseudo-angina pectoris from indiscretion in diet.

Chronic Dilatation.—Overfeeding and chronic indigestion are undoubtedly causes of dilatation of the stomach in infants and young children. Holt believes intestinal putrefaction exciting convulsions in young children to be an important factor in the production of epilepsy. Dr. Kemp regards acute dilatation of the stomach with convulsions as an equally powerful factor, when frequently repeated, in producing the convulsive habit, and thinks that some cases of epilepsy can certainly be attributed to this cause. Moreover, chronic dilatation of the stomach is itself one of the causes of intestinal putrefaction and disturbance. Among other etiological factors of chronic dilatation are chronic gastritis, atony of the stomach, rapid bolting of food, spasm of the pylorus due to gastric ulcer, and benign and malignant pyloric stenosis. Each case should receive the special treatment called for by the existing conditions. Dr. Kemp washes out the stomach often only in cases in which there is chronic gastritis with the production of considerable mucus, or when there is much retained food with fermentation.

Gastroptosis.—If gastroptosis exists, some enteroptosis necessarily accompanies it. The determination of the position of the stomach, in order to secure the best kind of treatment, is of great importance, and transillumination of the stomach he considers the ideal method for accurate diagnosis. The treatment consists in the following measures: (1) The correction of the functional derangement of the stomach by appropriate diet and medication; (2) regulation of the bowels; (3) mechanical support to increase the intra-abdominal tension, such as (*a*) various silk abdominal supporters; (*b*) bandages (as the Van Valzah-Hayes' method); (*c*) Gallant's corset; (*d*) Rose's plaster belt. He had seen some brilliant results from the last named. Recently he had employed for this belt rubber plaster on moleskin. The sweat evaporates through it on account of its loose texture, and it can be worn for quite a long time with practically no irritation.

Cases at the Manhattan State Hospital, Ward's Island.—Dr. Kemp presented colored diagrams made from forty epileptics in these institutions. The anatomical regions were marked out in blue pencil on the abdomen of each case, and during transillumination of the stomach the outlines of the organ were drawn in color. These markings were reproduced in the diagrams shown. Thirty-four of the patients were females. In 16 there was gastroptosis, in 16 dilated stomach, and in 2 the stomach was in normal position. In the 6 males

there were 5 dilated stomachs, while in 1 the stomach was in normal position.

Comparative Methods of Locating the Position of the Stomach.—Having stated that the standing posture was in general the most favorable for examinations, he spoke of changes in the position of the stomach due to ingesta. In the books it is stated that the empty stomach lies for the greater part of its extent beneath the ribs on the left side, extending a short distance below them, that when partially full it descends midway between the ensiform process and the umbilicus, and that when full it comes to within a few finger-breadths of the umbilicus. All this is true when the subject is in the dorsal position, since the suspensory ligaments of the stomach are relaxed, and as the organ fills up it gradually gravitates downward. In the standing position, however, as can readily be shown, the stomach, even when empty, at once descends to the full length of its suspensory ligaments, and its lower border is at a constant level, or within about an inch of the same, whether the organ be full or empty.

The Stomach Whistle.—To demonstrate this, Dr. Kemp devised a simple instrument known as the "stomach whistle," which consists of a rectal tube of small caliber with a whistle in the end. To it is attached an ordinary aspiration bulb without valves. The tube is inserted, the finger placed over the open end of the bulb, and a single bulbful of air forced into and aspirated out of the stomach by short and intermittent contractions. This entirely eliminates the possible chance of distending the stomach with air, and the organ remains practically empty. A stethoscope is placed on the abdomen, and the point of greatest intensity of sound is marked by a cross with a colored pencil. The tube is pushed in and out, and various points of sound are marked. The lowest is the lower border of the stomach. If gastrodiaphany is then performed, it will be found that the lower margins absolutely correspond. This is also a further evidence of the accuracy of the latter method.

Various methods of locating the stomach were tried on the same cases and, as a check, transillumination was employed as the last procedure in each instance. (1) Inspection was tried many times, but without success. (2) Carbonic acid gas often failed, and it was found impossible to regulate the amount of gas produced by the sodium bicarbonate and tartaric acid. (3) By administering small quantities of these drugs, with the patient standing, it is possible in a certain number of cases to map out approximately the lower margin of the stomach by listening with the stethoscope to the sound of the effervescence. (4) Inflation with air is advised by many authorities. The method may, however, sometimes cause great discomfort. It is liable to overdistend the stomach, and may even be a source of danger. On many occasions what was apparently stomach becoming protuberant on the abdominal wall was shown by transillumination to be intestine forced out laterally and forward by the stomach. (5) Simple percussion in various positions. (6) Auscultatory percussion. (7) Reichmann's auscultatory percussion rod. (8) Inflation with water seems to be a fairly good method, as it is easier to differentiate between dulness and tympanites than between the different forms of tympanites. (9) Inflation of the intestines with air is inaccurate. If water is employed, its acts as an enema. (10) The ideal method is transillumination, originally devised by Einhorn. As an improvement in technic Dr. Kemp has of late employed fluorescent media. By means of these he has found it possible to transilluminate the stomachs of fat subjects, which were formerly unsatisfactory, and, in general, the transillumination is increased nearly one-half. As a matter of scientific exactness, Dr. Kemp suggested the infusion of radio-active saline solutions into animals and also their hypodermatic use. The experiments made, however, showed no results from the standpoint of physiological medicine, and at present he felt that such solutions have no therapeutic value whatever.

The Relations of the Stomach to Auto-infections.—Dr. Wm. H. Thomson said he would confine his remarks to the relations of the stomach to certain auto-infections which seem to be chiefly caused by changes in the tone and motility of the stomach walls, which changes appear to be closely connected with the etiology of some common nervous derangements. In the first place, when a nervous disorder is intermittent, it may be assumed that it is one due not so much to a neurosis as to a toxemia. He had no doubt that the great majority of the attacks of epilepsy are primarily due to a toxemia. Nervous symptoms dependent upon organic changes are never intermittent, and while it is true that in some cases of epilepsy there is a persistent source of irritation in the form of an organic change produced by traumatism or a localized lesion, yet even here the attacks are intermittent; which could not possibly be the case if the traumatic irritant were the sole cause. Therefore, even in traumatic epilepsy something else besides the standing local irritation is required to develop the convulsive paroxysm, and that something is most certainly one of the forms of toxemia. He believed that in time a case of so-called idiopathic epilepsy may acquire an organic basis, on the principle that every nervous function which is not original to the cerebral cortex, but is acquired, has an anatomical basis there after the function has been acquired. Now apply this principle to nervous pathology. In the brain-training period of childhood let us suppose that an abnormal or diseased habit is being contracted by the special and selective operation of some blood-poison on a special cortical area. It is only consistent with general law that such poison may in time, by repeatedly acting on the same area, finally cause an anatomically organized area of morbid activity. While not denying that congenital malformations may in some instances be the origin of epilepsy, it may be inferred that the great majority of epilepsies are acquired. Hence the extreme practical importance of preventing epileptic attacks from becoming habitual, and, in order to accomplish this, of making every possible effort to discover the exciting causes of the attacks. Dr. Thomson said his criticism of the current views of the mechanism of an epileptic seizure was that it is looked upon as a primary discharge of cortical motor cells. But no motor cell ever discharges itself; it is invariably in response to some afferent excitation alone that such a discharge can occur. When we seek for causes of undue afferent excitability, it is only in toxemias that we find the most conclusive illustrations, and this should lead us to attach great importance to every means which will enable us to be more precise in our examination of the organs most concerned in causing auto-infection. Gastric atony and dilatation, for example, always imply not only deficiency of muscular power, but also qualitative changes in the normal secretions of the stomach; and it should never be lost sight of that all digestive secretions are also powerful antiseptics, so that deficiency or perversion of these of itself disposes to self poisoning. He welcomed, therefore, all measures which tend to improve our means of diagnosis.

Gastrodiaphany, or Transillumination of the Stomach.—Dr. Max Einhorn said that the great advantage of this method is that it affords an opportunity of examining the stomach in the natural state, and not when it is overdistended, as by gas. A great many mistakes

have been made in consequence of such overdistention, and the method of using effervescing mixtures is attended with some danger. Gastrodiaphany is undoubtedly a good method, but it is rather an elaborate one, requiring a dark room, an electric battery, and a special apparatus. It is particularly useful for gastroptosis and when tumors are present. For the general practitioner he thought the most serviceable method was the production of a splashing sound when the stomach is partially filled with liquid. This, he believed, affords the most accurate means of ascertaining the situation of the stomach and also the outlines of the organ. He would, therefore, place it first as a means of diagnosis.

Dilatation of the Stomach.—Dr. Geo. R. Lockwood said that if a stomach in the morning fasting state habitually contains food remains, or if it contains a greater amount of gastric juice than 100 c.c., it may reasonably be assumed that pyloric obstruction exists, no matter what the actual size of the stomach may be. We find large stomachs that are not to be considered as "dilated," since they are adequate in a muscular sense and empty themselves as they should; on the other hand, there are stomachs of normal or diminished size which are muscularly inadequate and do not properly empty themselves. The latter may be regarded clinically as dilated stomachs, although they are not dilated. To determine absolutely the actual size of the stomach we need to locate the two curvatures and the overlapping of the stomach area to the right of the median line. The lower curvature can be readily made out in the great majority of instances. In Dr. Lockwood's experience the results of gastrodiaphany have been most misleading, and he has of late excluded the method from the list of available means for diagnosis. He has obtained the most accurate results from inflation, combined with palpation and inspection; and next in order of value he would place the area of succussion sounds obtained. With an oblique light shining back of the recumbent patient, the shadow outline can usually be distinctly seen. If the upper curvature is not observed descending on inspiration, with the respiratory descent of the greater curvature, the diagnosis of an enlarged stomach can be made with reasonable certainty, and gastroptosis excluded. Inflation should regularly be practised by pumping air into the stomach through a tube, and not by the use of effervescing powders. In cases where such an inflation is inadvisable, a moderate inflation by effervescing powders may be made, and light percussion, preferably by auscultatory stroke percussion, employed. By observing changes in note before and after such inflation, colon tympany need not be mistaken for gastric. The area over which succussion sounds are heard affords very reliable evidence as to the position of the lower curvature. This sign is fairly accurate, provided there be no liquid in the transverse colon; a point which may be determined by tapotement in the cecal region. In normal cases the gastric tympany rarely extends beyond 6 c.c. to the right of the median line. An extension of the tympanic area to 8 c.c., or more, affords fair presumption of enlargement.

The detection of the upper border of a normally located stomach is almost an impossibility. Consequently the exact vertical dimension can rarely be determined. The estimation of the exact size is further rendered difficult by displacement downward of a dilated stomach, or its assumption of the vertical position. He thought the mistakes in diagnosis dependent on two errors: (1) In basing a diagnosis on the location of the greater curvature alone, forgetting that it might be a gastroptosis alone, or a displacement coexistent with a dilatation. (2) In making a diagnosis of dilatation from the size of the stomach alone; the sole sign of dilatation that is accurate being the detection of food remains or of contained secretion in a fasting stomach. No diagnosis, therefore, can be made without careful and, if necessary, repeated examinations of the gastric contents in the fasting state.

Gastroptosis.—Dr. Achilles Rose thought this term unfortunate, and preferred *gastroptosia,* which, correctly translated means abdominal tosis, not necessarily ptosis of the stomach alone. Gastroptosia also has the advantage of including the relaxation of the abdominal walls. Relaxation of the abdominal muscles forms a factor in gastroptosia, and it is the first factor we have to consider in therapy. Those who have used the term *atonia gastrica* in the sense of motor insufficiency of the stomach had caused much confusion, since atonia gastrica may exist without such insufficiency. Gastroptosia is identical with relaxation, and constitutes atonia gastrica. Atony may cause motor insufficiency, or, in turn, may be caused by insufficiency; but it may exist without insufficiency when the resistance at the pylorus is subnormal. Gastroptosia is never present without dilatation. Gastroptosia depends on relaxation, and relaxation of the fibers of muscles means elongation of the fibers; therefore relaxation is, *eo ipso,* dilatation. Many cases which were formerly classified as neuroses are now recognized as instances of gastroptosia with gastric and nervous symptoms. All forms of anomalous gastric secretion may be associated with gastroptosia, and prompt relief from such abnormal secretions and from motor insufficiency may often be secured by proper treatment of this condition.

Treatment.—In the treatment of gastroptosia the principle to be kept in view is relief from relaxation, and, first of all, from abdominal relaxation, by means of mechanical support of the abdominal walls. This can best be given in most instances by strapping in the way that has been suggested by Dr. Rose. Very often strapping alone, without any other treatment, will restore the secretory and motor functions of the stomach to a normal state. Gastroptosia may play a part in diseases of the organs of respiration and circulation, and in illustration he quoted a cardiac case reported by Groddeck. Dr. Rose said he could cite just as striking examples from his own experience, or he might refer to a patient he had seen under examination before a medical society. Everyone present studied the auscultation and percussion signs, but not a single physician took notice of the most remarkably pronounced gastroptosia existing. They all spoke of various remedies to improve the circulation, but not one had an idea of the most important of all the remedies called for in the case, the support of the abdomen.

The Surgeon's Point of View.—This was discussed by Drs. R. H. M. Dawbarn and George E. Brewer. The latter said the cases for operative interference could be divided into three classes: (1) Malignant disease; (2) benign disease, such as ulcers and, very rarely, tumors; (3) spasm, when surgical rather than medical aid is required; the condition having gone beyond the point when efficient relief can be afforded by medical remedies or mechanical support. In gastric ulcer it is universally conceded that one of the most essential requisites of successful treatment is rest, and there can be no question that in many instances a gastro-enterostomy affords an opportunity for the healing of the ulcer better than can be secured in any other way. The spasmodic conditions produced by ulcers can also be promptly remedied by surgery. The operations for the relief of the various forms of benign disease show a very low rate of mortality. In conclusion, Dr. Brewer made a suggestion as to the importance of the early recognition and early surgical treatment of dilatation in the "cancer age."

The surgeon is now, he said, making much earlier diagnoses of carcinoma than formerly. This is largely due to laboratory methods; but even these do not give the diagnosis in time to do a really radical operation. Whenever, therefore, a person at the cancer age has a sudden onset of digestive trouble, or a sudden increase in such trouble previously existing, suspicion should at once be aroused. An early exploratory incision is attended with a minimum of risk, and if malignant disease is discovered, it can be treated while the affected area is still very limited and glandular involvement has not as yet occurred. Only thus can the disease be reached at a time when it may be thoroughly eradicated, and by the adoption of this plan excellent results are now beginning to be shown.

The Relation of the X-ray and Radio-active Solutions to Examination of the Stomach.—Dr. Sinclair Tousey read a paper on this subject. He said he had repeatedly determined the presence of cancer of the stomach by the use of the X-ray alone. At present he is inclined to rely, in stomach work, more upon the fluoroscopic than upon the skiagraphic examination. Sometimes a tumefied anterior wall or pyloric extremity can be quite positively made out with the fluoroscope, and be merely indicated with a reasonable degree of probability by a skiagraph. In other words, a tumor of the stomach is almost transparent to the X-ray, and, being in constant motion during respiration, is better studied directly. Simple dilatation of the stomach and gastroptosis, without the presence of a tumor, would scarcely be capable of demonstration by the X-ray under ordinary circumstances; and it was with a view to the diagnosis of these conditions that his experiments were undertaken. Having given a résumé of his observations up to the present time, Dr. Tousey said that his conclusions, based on these, were as follows: (1) Radio-active and fluorescent solutions are innocuous when given by the mouth or subcutaneously; (2) they do not produce, either singly or in combination, sufficient fluorescence to be of value in the examination of the stomach without the use of some additional light to excite their fluorescence; (3) they will in some cases be of the very greatest assistance in the X-ray diagnosis of stomach lesions; (4) they will in some cases be of value in the X-ray treatment of stomach lesions.

SOCIETY OF THE ALUMNI OF CITY HOSPITAL.

113th Stated Meeting, Held March 9, 1904.

Erysipelas.—Dr. J. W. Draper Maury exhibited the graphic chart of a case of this disease which had been treated throughout with pure carbolic acid followed by alcohol. The chart showed an unmistakable and very immediate fall of temperature following the application of the acid, the variation in many instances during the five days covered extending over six degrees.

Experimenting with the McGraw Ligature.—He then presented a series of specimens of dogs' and pigs' stomachs and guts illustrating the recent experimental work done at the Surgical Laboratory of Columbia University. He said that at the suggestion of Dr. Weir, about a year ago, he had endeavored to use the McGraw elastic ligature in such a manner as to punch out a piece of the coapted viscera in gastro-enterostomy or in entero-enterostomy. Although the simple McGraw stitch has now been used many times on the human subject with perfect success by such men as Ochsner, of Chicago, and others, there exists a doubt in the minds of some surgeons that as patent and as lasting an orifice can be made with it as is produced by resection of the part at the time of operation or by use of the Murphy button. Dr. Maury believed that the stitch had now been so far perfected as to warrant one in stating with certainty that it would punch out all the material included within it.

Dr. Carter S. Cole, in opening the discussion of these specimens, said that the objection to such cumbersome mechanical devices as the Murphy button and their dangers were well known. He has for many years thought that a simple incision with ligature was better than any other technic. As to the erysipelas chart presented, he said that he was one of the first to use the method, having employed it seven or eight years ago. In his experience of thousands of cases demanding antiseptic treatment at the Hudson Street Hospital, he has found it the safest and surest manner of combating and preventing infection. He said that the time which should elapse between the application of the phenol and the brushing of the parts with alcohol depended on several factors. He cited the case of a shoemaker who, having a pain in his hip, by accident rubbed both hips with a pure carbolic solution thinking it was alcohol. A physician, who arrived twenty minutes after this was done, found both sides deeply eschared. He decided that it was hardly possible to prevent sloughing by the use of alcohol, but for the sake of experiment, painted one side with this fluid. The result was that despite the length of time elapsed, the untreated side went on to slough, whereas the tissue which had been swabbed with alcohol, recovered its normal condition in a few days.

Dr. Thomas F. Riley called attention to the very interesting fact that all the phenol group, when applied to the skin, tended to depress the temperature. Guaiacol and creosote will effect as extensive and as rapid a depression of temperature as phenol. He therefore felt that there was some reason to doubt whether the variations in the chart shown were due to the destruction of the *Bacillus erysipelatous*, as Dr. Maury and others had thought or to the foregoing influence. It was interesting further to note that while the progress of the disease had been checked from passing from the trunk to the thighs by deeply burning the latter with the phenol, nevertheless the infection had spread all over the torso and arms, although the treatment had been used with sufficient vigor to produce blistering in several places.

Dr. J. F. Terriberry said that in his experience tincture of iodine applied locally and croton oil applied internally is a combination which acts very well.

Dr. Cole in answer to some criticisms on the danger of pure carbolic, said that in the Hudson Street Hospital, he and his assistants used it as free as water, and that in his experience of several thousand cases, he never had seen even a suggestion of poisoning from the use of pure acid. The explanation of this is that it destroys the avenues of ingress and therefore is not absorbed by the system as is the case with weak solutions. The time elapsing between the application of the phenol and the swabbing with alcohol is determined entirely by the result which is sought. The drug first irritates, then stimulates, then produces anesthesia and lastly destroys the part. A practised eye can determine when each of these stages is reached.

Dr. Maury, in closing the discussion, said that in using the elastic ligature, it was not necessary to freshen the peritoneal surfaces which it brought into contact, the trauma produced by the technic being all sufficient to cause the parts to adhere very firmly. An interrupted Lembert line of sutures should be so placed as to securely enclose the ligature. The results obtained by the technic at present used in the Surgical Laboratory have been very encouraging.

The Prevention of Diseases of the Accessory Sinuses.—Dr. D. Bryson Delavan read this paper. He said that very special import had been given to this neglected subject by the advent to the city of a pecu-

liarly infectious form of grip. Many of these cases, instead of developing into pneumonia, had insidiously but often seriously involved the accessory sinuses, and he believed that a repetition of warnings previously given by him to the profession would not be out of place. Next to prevention, he said that early recognition and treatment of acute attacks of involvement of the mucous membranes of the respiratory tract were of paramount importance. As elsewhere in surgery, free drainage from the upper half of the nasal cavity is essential in every case. Malformations of the middle turbinated bone and displacements of the septum are among the most frequent causative factors in sinus disease. The exciting causes of sinus disease are varied. Inflammatory change may be brought about in many acute infections such as pneumonia, diphtheria, measles, scarlet and typhoid fever, smallpox, cerebrospinal meningitis, erysipelas and grip. Many cases are undoubtedly directly due to the inhalation of dust in our windy and filthy streets. Wind is due to other causes than to high buildings. Inveterate users of the open automobile are beginning to show that this machine is causing many serious sinus affections. Favorable results can usually be obtained by a prompt and thorough treatment of most cases of sinus inflammation due, as it often is, to the insidious disease known as grip; it should be watched with care and treated from the onset as a disorder likely to produce serious results. As in other conditions satisfactory treatment of the acute conditions will render chronic cases very rare. The principles of treatment are simple, being based entirely upon the conception that the condition arises from retention of secretions through blocking of the outlets. The indication is to drain and to clean. The congested and swollen parts may be contracted by suitable applications and free drainage will result without surgical intervention. A depletion of the nasal circulation is of the first importance. Drugs, however, are by no means the only method of obtaining this end. The heart must be kept quiet, and rest in bed, an even temperature, mild catharsis may all be indicated. Belladonna or aconite, or in cases of severe neuralgia, phenacetin and salol are the author's favorite drugs. The local treatment is of paramount importance and it should be borne in mind that this should be absolutely non-irritating and painless. The secretion should be gently removed from the surface and a spray of two per cent. solution of cocaine thrown upon the mucous membrane affected. After this drug has contracted the lower part of the nasal cavity, a spray of adrenalin or, preferably, a solution of the extract of suprarenal gland may be thrown as far upward as possible. The alternation of these two drugs may be necessary more than once. During the time of contraction of the membrane, there will be free discharge from the sinuses, and although the openings may close within a few hours, the relief afforded is usually sufficient to prevent a chronic involvement. It may be necessary to utilize this method several time a day. In this case the use of cocaine will of course be admissible because of the danger of inflicting the habit. In general the writer concluded that much could be done in the prevention of sinus disease by a recognition of the conditions under which it is likely to occur; by removal or mitigation of these conditions after their detection; by applying immediate treatment to those cases in which acute inflammation had begun.

Dr. D. H. Wiesner said that the subject of this paper could not be treated lightly. The amount of dust in the streets of our great cities is almost inconceivable, and the amount of damage done to our mucous membranes and sinuses is absolutely unknown. He agreed with Dr. Delavan that the use of cocaine for the relief of nasal engorgement was a very dangerous procedure.

Dr. W. B. Johnson said that a great many people suffered from acute attacks of sinusitis which were merely of a catarrhal kind and which, as was well known, in the case of the mastoid, will not go on to suppuration. The suggestions given as to methods of preventing suppuration were very useful. Adrenalin, he said, might in some individuals prove to be a severe irritant, one of his patients having had to sneeze for two hours after a single application of one to one thousand. Crushing the turbinate bone, as has been recommended by some Europeans, is absolutely non-surgical and contraindicated.

Dr. George B. McAuliffe called attention to the very interesting fact that ethmoiditis and probably other sinus invasions could actually be caused by the continued use of cocaine. He emphasized the importance of the element of rest. This is a most potent curative agent for that large class of persons who are unable to see their physician two or three times a day. These people should be put in a semirecumbent position and given aconitia, which is better than aconite, because it can be absolutely graded; one five-hundredth of a grain every hour. He spoke of the dreadful danger of cocaine, and suggested that if it must be used, adrenalin should be employed first, so as to limit the cocaine absorption as far as possible.

Dr. P. B. Hough said that he had not found it necessary to use cocaine in but very few cases, a mild alkaline spray serving the purpose sufficiently well and with less danger.

Dr. Delavan, in closing, said that the general practitioner neglected these cases so extensively that even today cases in which destruction of the organ of special sense had gone on almost to completion, were not rare. While extensive operations for these cases may primarily give good results, ten years later they may prove to be wofully unsatisfactory. He said that the internal use of drugs is undeniably important. For years, professional singers and others have used aconite. As for the cocaine habit, he believed that the uncomfortable period can best be bridged over by suprarenal extract. He considered it better than adrenalin, in that it is less expensive and has not the irritating qualities of the extract.

Personal Experience in the Treatment of Typhoid Fever.—Dr. Carter S. Cole said that it would be idle in the few moments allotted him to give even a summary of this subject. He said that our individuality must be impressed upon our work and it was with this understanding that he presented a view of his experience in treating this all too common and too frequently fatal disease. In 1887, he stated that in his opinion a nurse who was fitted to properly care for a case of typhoid needed no other testimonial to her ability in her profession. Fifteen years of practise have convinced him of the truth of this statement and furthermore that the physician who is abreast of every possibility in that disease is thoroughly competent to care for any conceivable ill of mankind. The author then considered the relation of treatment to temperature. The latter, he said, was a necessity. Every case of typhoid has its own peculiarities, not only in regard to temperature variation but also as to nutrition, intestinal and nervous conditions, etc. One patient has a high fever with an eruption from his neck to his feet; the other never has a temperature over 101° F. and has an almost imperceptible abdominal rash. The one is delirious almost all the time and dies of cardiac failure at the beginning of the fifth week. The other is never delirious but has almost a melancholia from which he does not recover for nearly a year. A child has a frightful attack of typhoid of the high-fever type, with profuse eruption, accompanied by pneumonia in the original attack and by an infection of the large intestine in the relapse. Her nurse contracts

the disease and has a comparatively simple attack, with few spots, with low temperature, her chief difficulty being an ever-present nausea. The first is fatal; the second makes a good recovery.

Dr. W. L. Baner, in opening the discussion of this paper, said that he considered the feeding of typhoid patients the most important part of the treatment of the disease. No more food than can very easily be digested should be given. He did not consider a widely distributed and very marked eruption such as Dr. Cole had described to be necessarily significant in determining a bad prognosis. These cases often do well and it has been noticed that they generally give a very positive reaction to the tests for the disease.

Dr. W. Ridgely Stone considered that temperature alone was but a poor indication for typhoid baths. History repeats itself over and over again in showing that low temperatures in typhoid often end fatally. It is rather the nervous and circulatory symptoms which call for hydrotherapy, the mere question of temperature being a matter of small import.

Dr. Cole, in closing, said that he considered the temperature to be a normal condition and used it simply as a guide for the nervous condition. He considers that the baths are very efficacious in reducing abdominal distention. As to the eruptions, if they be ubiquitious and more or less confluent, which is the type dwelt upon in his paper, the giving of a hopeful prognosis is, in his opinion, a very doubtful procedure.

BOOK REVIEWS.

The Practice of Obstetrics. Designed for the Use of Students and Practitioners of Medicine. By J. Clifton Edgar, Professor of Obstetrics and Clinical Midwifery in the Cornell University Medical College; Attending Obstetrician to the New York Maternity Hospital. With 1221 Illustrations, many of which are printed in Colors. P. Blakiston's Son & Co., Philadelphia.

The increasing interest in scientific obstetrics which has gone hand in hand with the development of gynecology has led to the appearance of numerous excellent treatises on this subject during the past few years. Few medical subjects require so much illustration or lend themselves so readily to pictorial embellishment and modern publishers have not been slow to avail themselves of the opportunities offered for the production of attractive books. It must be confessed, however, that this volume with its twelve hundred excellent pictures puts them all to the blush and stands *facile princeps* at the head of all text-books of midwifery.

The arrangement adopted by the author is a marvel of simplicity and is rendered still more practical by the ingenious system of subheadings in different styles of type consistently carried through the entire book. The subject-matter is divided into ten parts as follows: Physiology of the Female Genital Organs, Physiological Pregnancy, Pathological Pregnancy, Physiological Labor, Pathological Labor, Physiological Puerperium, Pathological Puerperium, The Physiology of the Newly Born, The Pathology of the Newly Born, Obstetric Surgery. A formal section on Anatomy has been omitted since discussions of the gross and minute anatomy of the pelvic viscera appear in appropriate places in the parts on pregnancy and labor.

The work throughout gives evidence of the greatest possible amount of thought and care devoted to the production of a book, detailed and comprehensive yet practical and convenient for reference, at the same time useful to the student and to the clinician. The statistical data on which the author's conclusions are based include 2,200 cases from the New York Maternity Hospital and from the Mothers' and Babies' Hospital.

In many ways the book differs from the stereotyped form of obstetrical treatise and gives information of a type often slighted in the standard works. Such for example is the section on monstrosities which contains 144 illustrations of the different forms of abnormalities encountered. Other chapters to which the author evidently attaches considerable importance are those on the diseases of the newly born, pelvic deformity, obstetric surgery, cephalometry and the mechanism of labor.

Of the very numerous illustrations little but praise can be said. They have been chosen with remarkable discrimination and form one of the noteworthy features of the book. In spite of their large number they nearly all serve a distinct purpose though the captious might perhaps think that figures 190-195 which depict respectively, properly and improperly groomed fingernails, pushing back the cuticle with an orange stick, the orange stick, cleaning the nails with a towel, a hand in a rubber glove and a commerical can each of washing soda and chlorinated lime, do not represent concepts so foreign to the mentality of the average medical reader as to require graphic representation.

It is a great pleasure to be permitted to call attention to what undoubtedly is, and probably will long remain, our foremost handbook of obstetrics.

Medical Union Number Six. By William Harvey King. The Monograph Press, New York.

This is a pamphlet written supposedly to show to what absurdities and even loss of life trades unionism would go if pushed to an extreme. Just why the author should have made the medical profession the butt of his observations is hard to understand. The book is not likely to have any influence either for or against the important principles that underlie union for the purpose of securing due rights and which, like every other good thing in life, may and will be abused, but from the abuse of which no argument holds against the proper use.

The Treatment of Fractures. By C. H. Scudder, M. D. Fourth Revised Edition. W. B. Saunders & Company, Philadelphia, New York and London.

The appearance of the fourth edition of this work within a period of four years testifies to its popularity and value. As stated in the author's preface, the book is intended to serve as a guide to the student and practitioner in the diagnosis and treatment, and the latter is illustrated as thoroughly as possible. Mechanical simplicity is advocated. Recognized essentials are an exact knowledge of anatomy combined with accurate observation. A prominent feature of the book is the wealth of illustrations, of which the greater part are from new and original drawings and photographs. The hackneyed cuts of common fractures and dislocations which constantly find a place in one book on surgery after another, are wisely omitted and their place taken by newer and better representations. Naturally X-ray pictures play an important part, and especially interesting are those of the epiphyses at different ages. The question of treatment is very fully considered, the details in the various steps of reduction and the application of splints being in many cases depicted in a series of illustrations. A valuable chapter on X-rays and their interpretation, by Dr. Codman, is appended and also one on terial infection, and are therefore less misleading. The application of the plaster-of-Paris bandage, containing many new and valuable hints.

LESIONS PECULIAR TO THE PANCREAS AND THEIR CLINICAL ASPECT.[1]

BY EUGENE L. OPIE, M.D.,
OF BALTIMORE, MD.

To the clinician the characteristic feature of pancreatic disease is doubtless the obscurity of its symptoms. Though the gland is one of the most important organs of the body, subserving a considerable variety of diverse functions, extensive destructive changes are often unaccompanied by recognizable symptoms. This obscurity is due to a variety of causes. The organ is situated in contact with the vertebral column and unlike the liver is rarely palpable either in health or disease. The secretion elaborated by the pancreas plays an important part in the digestion of proteids, fats and carbohydrates, yet only when the pancreatic juice is wholly or almost wholly prevented from reaching the intestine does the resulting disturbance of digestion give indication of pancreatic disease. Occlusion of the bile duct causes the accumulation of bile in the tissues and its excretion in the urine, but occlusion of the pancreatic duct causes neither the accumulation nor excretion of any product which is so readily recognized as the bile pigments. Grave lesions of the pancreas are accompanied by the disorder of carbohydrate metabolism, diabetes mellitus, but the diagnostic value of glycosuria is modified on the one hand by the occurrence of diabetes without disease of the pancreas, and on the other hand by the absence of diabetes with many lesions of the gland.

Recognition of pancreatic disease is further complicated by the fact that lesions of the gland are seldom primary, but are dependent upon changes in other organs, notably in the duodenum, liver or bile passages. Nevertheless, the knowledge that certain lesions of the pancreas are frequently found in association with more readily recognizable conditions will in many instances give evidence that the gland is diseased. An understanding of the peculiar pathology of the pancreas and of its relation to that of other organs is therefore essential to the diagnosis of pancreatic disease.

The pancreas, unlike all other glandular organs, consists of two elements which differ so much in structure and function that it is necessary to consider separately the diseases which affect them. Secreting cells which elaborate the ferments of the pancreatic juice are in communication with a system of ducts carrying the products of secretion to the duodenum. Embedded among the secreting acini are small round bodies which can barely be recognized by the naked eye. The cells which form such bodies, differ from those of the secreting acini; they do not communicate with the ducts, and take no part in the manufacture of the pancreatic juice. They are, however, in intimate contact with dilated capillary vessels, and abundant evidence has shown that through the medium of the blood they exert an important influence upon metabolism. These structures which resemble certain other ductless glands, the parathyroid bodies, the adrenals and the thyroid gland, are the so-called islands of Langerhans.

Diseases of the pancreas, therefore, may be conveniently separated as follows: first, those which affect the secreting apparatus of the gland and, second, those which have their seat in the islands of Langerhans and interfere with the influence which these structures exert on carbohydrate metabolism.

Before considering those lesions which affect the secreting apparatus of the gland I will mention certain recently demonstrated facts concerning the physiology of the pancreatic juice, the so-called external secretion of the organ. Even though their bearing upon clinical medicine and upon pathology may not as yet be evident they serve to show the complexity of the pancreatic functions.

Most important are the observations of Pawlow and his pupils. The pancreatic juice contains three ferments which have a preeminent part in the digestion of the three most important constituents of the food. In the cells of the pancreas the precursors of these ferments exist as zymogens, so that an extract made from fresh pancreatic tissue is capable of digesting proteid only after the contained zymogen has been converted into trypsin. Pancreatic juice obtained from a pancreatic fistula in the dog is capable of only weak solvent action upon proteid material. Schepowalnikow, a pupil of Pawlow, has shown that the intestinal secretion, the succus entericus, to which heretofore little significance has been accorded contains a ferment which acting upon the pancreatic juice enormously increases its power to digest proteid substances, such as fibrin or coagulated egg albumin. Pawlow believes that the proteid-digesting ferment of the pancreatic juice is excreted in the form of inactive zymogen which is converted into active trypsin by the action of a second ferment contained in the succus entericus of the duodenum. To this ferment of a ferment, as he describes it, he has given the name enterokinase.

Enterokinase, moreover, exerts an augmenting action upon the fat-splitting ferment of the pancreatic juice, but here comes into play a second

[1] Presented February 4, 1904, before the New York Academy of Medicine, at a meeting devoted to the consideration of Disease of the Pancreas.

factor which has an important bearing upon the etiology of acute hemorrhagic pancreatitis and the associated fat necrosis. Bruno another pupil of Pawlow has emphasized the fact, already known, that the bile affords a favorable medium for the action of the pancreatic ferments and particularly of the fat-splitting ferment, which may be increased in efficiency two or threefold. This favoring action of the bile is due to its chemical constitution and not to a ferment like enterokinase. Pawlow and his pupils have clearly demonstrated the important fact that the activity of the pancreatic juice is in considerable part dependent upon the secretions with which it comes in contact after it has entered the intestine.

A consideration of pancreatic disease may well be introduced by a few remarks concerning the effect of pancreatic juice diverted from its proper channels into the tissues about the organ. When the common bile duct is occluded, bile is dammed back upon the liver and is transported to all parts of the body. Jaundice is readily recognizable because bile pigments are present in the conjunctiva and in the skin, while the characteristic color and certain chemical reactions readily establish their presence in the urine. When, however, the secretion of the pancreas is diverted from its normal channel, no pigmented constituent gives evidence of its presence in the tissues, nor have we, as yet, any certain means of demonstrating the presence in the urine of substances formed in the pancreas.

Nevertheless, pancreatic secretion which has found its way into the tissues causes a characteristic lesion, but since this lesion is usually confined to the adipose tissue of the abdominal cavity it has diagnostic significance only to the surgeon who opens the abdomen. I refer to the so-called fat necrosis which occurs only in association with disease of the pancreas. Circumscribed opaque white foci of necrosis are conspicuous upon the translucent yellow fat of the omentum, of the mesentery, and below the parietal peritoneum, and are recognizable as soon as the peritoneal cavity is opened. In the neighborhood of the pancreas necrotic areas are large and often confluent. In cases where the lesion is recognized examination of the organ at operation reveals one of a variety of changes. Acute hemorrhagic pancreatitis is most frequently associated with fat necrosis; suppurative pancreatitis is less commonly found accompanying it. Fat necrosis may accompany chronic interstitial pancreatitis, or obstruction of the pancreatic duct caused by biliary or pancreatic calculi, or by carcinoma compressing the duct. In order to explain the relation of fat necrosis to these various lesions it is necessary to briefly describe its pathogenesis.

Langerhans showed that death of the fat cells is associated with the splitting of their contained fat into glycerin, which being soluble is carried away, and insoluble fatty acids, which remaining are recognizable within the dead fat cells. Flexner was able to demonstrate in the foci of necrosis a fat-splitting ferment which is doubtless identical with that of the pancreatic juice. That necrosis of fat is in reality caused by the penetration of pancreatic juice into the tissues is well illustrated by the following experiment: When in the cat both ducts of the pancreas are securely ligated, death with necrosis of almost the entire abdominal fat results within several weeks, being caused presumably by pancreatic juice which is dammed back upon the gland. If after the ducts are ligated pilocarpine, which stimulates the pancreatic secretion, is administered to the animal, fat necrosis of the same extent results within several days. Moreover, those lesions of the pancreas which cause fat necrosis are such as favor the penetration of the pancreatic ferments into the tissues about the pancreas.

Fat necrosis for the surgeon may often serve as an index to pancreatic disease and recognized during the course of an exploratory laparotomy has not infrequently explained an otherwise wholly obscure case. In the majority of instances fat necrosis implicating the omentum, the mesentery and perhaps the fat of the parietal peritoneum, is caused by the condition known as acute hemorrhagic pancreatitis.

Acute hemorrhagic pancreatitis primarily affects the secreting apparatus of the pancreas and is doubtless in all instances dependent for its origin upon the peculiar anatomical and physiological characters of the gland. The disease is uncommon, but of such severity that death may result within forty-eight hours after the onset of symptoms. In the more typical cases an individual, often in good health, who perhaps has suffered with previous attack of abdominal pain is suddenly seized with intense pain in the epigastrium, soon accompanied by uncontrollable vomiting, and followed by very profound collapse. The localization of the pain and the severity of the symptoms are the most characteristic features of the disease and in a certain number of cases make a diagnosis possible. Not infrequently the symptoms, though of the same character, are less severe, the individual survives several weeks, abdominal pain continues, and an ill-definable tumor mass appears over the region of the pancreas. Septic fever, leucocytosis and other evidence of suppuration give indication of a peripancreatic abscess limited by the lesser peritoneal cavity.

Examination of the pancreas of individuals who have died within three or four days after the onset of such symptoms shows the characteristic lesion of acute hemorrhagic pancreatitis. The organ is very greatly enlarged and infiltrated with blood, which soon assumes a reddish black or black color. Microscopical examination shows that the tissue of the gland has in great part undergone necrosis. Study of the etiology and pathology of this remarkable condition has added an important fact to its somewhat obscure symptomatology.

A review of cases contained in the somewhat voluminous literature of the subject has shown that a considerable proportion are associated with gall-stones present in the gall-bladder or in the bile passages. I have collected 41 such cases

from the literature, and doubtless in many other instances their presence has been overlooked or unrecorded. In four of five cases which have come under my observation gall-stones have been present.

A case which I have described and since frequently cited serves to explain the relation between cholelithiasis and acute hemorrhagic pancreatitis. Examination of the pancreatic and common bile ducts in this case has pointed to a mechanism capable of causing the lesion, and clinical and experimental observations have clearly shown that this mechanism is the etiological factor in many, if not in all, cases. The larger duct of the pancreas, the duct of Wirsung, and the bile duct, it is well known, join before entering the intestine and in most cases form a short common channel known as the diverticulum of Vater. In the case referred to a small gall-stone had so lodged at the orifice of this diverticulum that it had converted the two ducts into a continuous closed channel from which neither the bile nor the pancreatic juice could escape. Bile had penetrated into the pancreatic duct, doubtless injected as it were by the gall-bladder, and had caused characteristic staining of this duct by bile. The pancreas was the seat of extensive hemorrhagic necrosis.

A review of 41 reported cases in which gall-stones have been found in association with acute pancreatitis, has shown that in seven instances a calculus was lodged at the duodenal orifice of the common bile duct so that, as in the case I have described, mechanical conditions favored the penetration of bile into the pancreas. In a case of acute hemorrhagic pancreatitis, reported by Dr. Thayer, the orifice of the diverticulum of Vater was much dilated and the calculus which had been recently expelled was found within the lumen of the duodenum. Doubtless in many instances the calculus lodges only temporarily within the diverticulum of Vater and escapes into the intestine.

It has long been known that a variety of irritant substances including various acids and alkalies injected into the pancreatic duct of animals causes typical hemorrhagic pancreatitis with disseminated fat necrosis, but there is little probability that such substances ever enter the duct in man. Directed by the suggestion which the foregoing cases offer I have performed a series of experiments to determine if bile injected into the pancreatic duct can cause the lesion. Typical hemorrhagic pancreatitis accompanied by disseminated fat necrosis has resulted when the bile of one dog has been injected into the pancreatic duct of a second. The result is not surprising, since the number of irritant substances which produce the lesion experimentally is considerable. Necrosis with hemorrhage resembling that which affects the pancreas does not occur in other organs as the result of similar irritation. The gland secretes ferments which are capable of digesting its own substance, but for reasons which as yet are not entirely clear the living cells of the gland are protected from self-digestion. When, however, the tissue is injured by the presence of bile or other irritant substance the pancreatic ferments doubtless cause further destruction. Physiological observations from the school of Pawlow, already cited, have a bearing upon the present subject; in the presence of bile the activity of the pancreatic ferments is increased. That the activity of the fat-splitting ferment is especially augmented may explain the wide dissemination of fat necrosis in association with acute hemorrhagic pancreatitis.

The clinical aspect of the facts just described is the following: (1) The presence of jaundice, or the history of previous attacks of gall-stone colic may give confirmation to the diagnosis of acute hemorrhagic pancreatitis when somewhat indefinite symptoms suggest the presence of this condition. (2) When at operation undertaken for the relief of obscure abdominal symptoms, disseminated fat necrosis indicates the presence of acute hemorrhagic pancreatitis, examination of the gall-bladder and bile passages will in a considerable proportion of cases reveal the presence of gall-stones. Their removal offers the best chance of recovery.

In a woman, forty-one years of age, recently under the care of Dr. Howard A. Kelly, disseminated fat necrosis noted at operation suggested the presence of acute pancreatic disease, and the well-marked enlargement of the pancreas confirmed the diagnosis. The gall-bladder contained a large number of small gall-stones. Cholecystotomy with removal of the calculi was followed by recovery.

It is noteworthy that in this case and in another in which acute pancreatitis was associated with cholelithiasis, recognized, however, only at autopsy, the patient passed clay-colored stools.

The occurrence of acute hemorrhagic pancreatitis in association with cholelithiasis adds another to the grave complications of the latter disease. Compared with cholelithiasis, however, acute hemorrhagic pancreatitis is a very rare disease. Since the lodgment of a calculus in the diverticulum of Vater may cause this lesion of the pancreas, it is pertinent to inquire why it does more frequently follow the expulsion of gall-stones from the common bile duct into the duodenum. Certain conditions must be fulfilled in order that a calculus can convert the bile and pancreatic ducts into a continuous closed channel. On the one hand the calculus must be of such small size that it is capable of occluding the duodenal orifice of the diverticulum without obstructing the two ducts that enter it. In all of the cases of acute pancreatitis which I have examined the gall-stones present in the bile passages and in the gall-bladder have been of very small size. On the other hand the anatomical conformation of the diverticulum of Vater in a considerable proportion of all individuals is such that the mechanism described could not result even were a gall-stone of suitable size lodged at the common duodenal orifice of the two ducts. In one of ten

individuals the pancreatic and bile ducts have no common channel, but open side by side at the summit of the bile papilla. Indeed, in only 32 of one hundred specimens which I have examined, was the diverticulum so formed that it could obstruct the passage of a calculus which would not completely fill it. In only three of about ten individuals, therefore, are the anatomical conditions such that a small calculus might divert bile into the pancreatic duct.

What has been said in regard to acute hemorrhagic pancreatitis applies with some modification to the condition known as gangrenous pancreatitis, which is a secondary stage of the hemorrhagic lesion. Gangrenous pancreatitis is usually associated with suppuration limited to the lesser peritoneal cavity, and its treatment is that of localized peritoneal abscess.

Another lesion which has its origin in the secreting apparatus of the pancreas is the chronic inflammation which follows obstruction or ascending infection of the pancreatic ducts. When the pancreatic ducts of an animal are ligated, chronic inflammation rapidly ensues and bands of thickened connective tissue are formed between the lobules which make up the organ. The human pancreas is provided with two ducts which in most instances anastomose within the gland, but in the great majority of cases the lesser duct which has its orifice nearer the stomach is so narrow that it is incapable of acting as an outlet for the entire pancreatic secretion. In man, as in lower animals, occlusion of the ducts is followed by chronic inflammation characterized by the formation of thick interlobular bands of fibrous tissue. Extensive destruction of the secreting acini results, but there is a well-marked tendency to spare the peculiar islands of Langerhans already mentioned. These are implicated only when the lesion is far advanced.

Occlusion of the larger pancreatic duct is most frequently caused by calculi formed within the pancreas, by biliary calculi or by carcinoma compressing the duct. It is in such cases, especially, that the digestive disturbances usually attributed to pancreatic disease have been observed. Prof. Fitz has collected from the literature 29 cases of pancreatic disease in which fatty stools were noted during life. In 14 cases cancer was present, in seven, calculi, and in two additional instances the pancreatic duct was obstructed. The small number of these cases indicates how infrequently fatty stools serve to aid the diagnosis of pancreatic disease.

Particularly noteworthy is the fact that obstruction of the pancreatic duct and consequent chronic inflammation of the interlobular type may be caused by a biliary calculus which has lodged in the common bile duct near its duodenal orifice. A small gall-stone impacted at the orifice of the diverticulum of Vater might cause acute hemorrhagic pancreatitis by diverting bile into the pancreatic duct in the manner already described, but a larger stone would completely fill the common part of the two ducts and cause obstruction both of the bile duct and of the pancreatic duct. Chronic inflammation of the gland would result, particularly since the bile passages in such cases are not infrequently the seat of infection and perhaps of suppurative inflammation.

Both Riedel and Mayo-Robson have emphasized the surgical importance of recognizing chronic interstitial pancreatitis in association with gall-stones. Both have pointed out that in a certain number of operations undertaken for relief from gall-stones the head of the pancreas is found to be so indurated that the existence of carcinoma is suspected. Indeed, in several instances a grave prognosis has been based upon the discovery of this induration, but the subsequent recovery of the patient has disproven the diagnosis of malignant disease. Mayo-Robson, who has described several cases in which chronic interstitial pancreatitis accompanied cholelithiasis, attaches considerable clinical importance to the former condition, believing that it causes severe pain in the epigastrium and in the midscapular region, vomiting at times, loss of weight and strength, and even death with increasing weakness. Cholecystotomy with drainage of the gall-bladder, and, when necessary, removal of the gall-stones has been followed by recovery.

In three cases seen at autopsy I have found chronic interstitial pancreatitis in association with cholelithiasis. In one case a large gall-stone was lodged near the duodenal end of the common bile duct, in such position that it compressed the pancreatic duct as it entered the diverticulum of Vater. In the other two cases, though at autopsy no calculi were found in the common bile duct, it is not improbable that chronic pancreatitis may have resulted from their former lodgment in this position.

The lesions previously described have had their origin in the secreting apparatus of the pancreas. When they cause complete destruction of the organ they necessarily inhibit all its functions. Another group of lesions, however, inhibits primarily that influence which the organ exerts on metabolism through the medium of the circulation, that is, the so-called internal function.

Clinical observation, inaugurated by Thomas Cawley as early as 1788, has shown that diabetes mellitus is frequently associated with grave disease of the pancreas, but the relationship of the pancreas to carbohydrate metabolism has not been clearly recognized until von Mering and Minkowski succeeded in completely extirpating the organ in dogs. Their experiments, which mark an epoch in the knowledge of diabetes, demonstrate as is well known, that sugar appears in the urine within a few hours after the complete removal of the gland. Glycosuria continues, the animal develops symptoms which are analogous to those of human diabetes, and death results after several weeks. Such experiments prove that in the absence of the pancreas the tissues of the body are no longer able to assimilate sugar; it accumulates in the blood and is excreted by the kidneys.

The relationship of the pancreas to carbohydrate metabolism can be shown in other ways. Particularly noteworthy are the recent observations of Dr. Herter who has found that adrenalin chloride painted upon the pancreas of dogs causes temporary glycosuria lasting several hours. When oxidized this substance no longer has the same action. By subsequent observations he has shown that a considerable number of diverse substances, which in general may be grouped together as reducing agents applied to the surface of the pancreas, cause glycosuria.

The pancreas is essential to normal carbohydrate metabolism, but how it acts has long been obscure. It has been maintained that the organ furnishes to the blood some substance, a hypothetical internal secretion, which is capable of decomposing sugar. The French chemist, Lepine, has claimed that the blood of normal animals contains a glycolytic ferment which is absent in animals deprived of the pancreas, but these observations have not been confirmed. Investigations of Otto Cohnheim appear to have supplied evidence that the pancreas furnishes to the blood a ferment which controls the metabolism of sugar. Cohnheim directs attention to the well-known fact that sugar in large quantity is broken up in the muscles, presumably by the action of some ferment; yet it is not possible to obtain from the muscles a ferment which has a noteworthy glycolytic action. By the use of special apparatus muscle is frozen, very finely divided, and subjected to a pressure of three hundred atmospheres. The fluid which is expressed does not cause the decomposition of grape-sugar, but if it is mixed with fresh pancreatic tissue similarly treated, the expressed juices thus obtained have the power to break up grape-sugar so that it is no longer recognizable by its reducing action. This glycolytic action is accomplished by neither organ acting singly, but by the two in combination. The change is doubtless referable to two ferments which bear to one another a relation similar to that which the enterokinase of Pawlow, already mentioned, holds to the trypsinogen of the pancreatic juice, the first being capable of bringing the second into action. Hence it appears that the pancreas furnishes to the blood a ferment which acting upon the muscle makes it capable of assimilating grape-sugar.

In animals complete extirpation of the pancreas is followed by diabetes, partial extirpation of the gland is followed by diabetes only when the part remaining represents a very small fraction of the whole organ. Destructive lesions of the pancreas are accompanied by diabetes when almost the whole organ is implicated, but when a considerable part is unaffected glycosuria is absent. Hence it results that acute hemorrhagic pancreatitis is seldom accompanied by glycosuria. In only two of 41 cases of hemorrhagic pancreatitis and in but three of 40 cases of gangrenous pancreatitis collected by Körte was sugar present in the urine. The necrosis characteristic of both the hemorrhagic and gangrenous lesion rarely if ever causes complete destruction of the gland, and in most instances leaves uninjured a part sufficient to carry on the internal function of the organ. Carcinomatous new growth invading the gland and replacing the parenchyma may so completely destroy the organ that diabetes results. It is evident, therefore, that diabetes mellitus, or at least glycosuria, may be regarded as a symptom of pancreatic disease.

Of the pancreatic lesions which have been found associated with diabetes doubtless the most common is chronic inflammation causing an increase of the interstitial tissue of the gland. Chronic interstitial pancreatitis is, however, more common than diabetes and is in the larger number of cases unaccompanied by the disease. Reference has already been made to the chronic inflammation which follows obstruction to the outflow of the pancreatic juice. The lesion which results is probably due in part at least, to infection of the stagnant secretion with bacteria from the duodenum, and a similar lesion may occur in consequence of ascending infection of the duct without occlusion. When chronic pancreatitis has its origin in the pancreatic ducts, newly formed tissue makes its appearance as course bands separating lobules and groups of lobules, the secreting parenchyma undergoing a variable degree of destruction. The ductless structures known as islands of Langerhans, on the contrary, are almost wholly unaffected, and often persist, though the parenchyma which previously surrounded them has been completely destroyed and replaced by dense fibrous tissue. This type of chronic pancreatitis, which may be designated interlobular, has been described in order that it may be distinguished from a second less frequent type characterized by the presence of fine strands of newly formed fibrous tissue within the lobules and between the secreting acini. While with the interlobular type of inflammation the islands of Langerhans are spared, with this second type which may be designated interacinar, since the new tissue penetrates between the secreting acini, the islands of Langerhans are invaded and their cells destroyed.

It has been necessary to discuss the histological details just cited in order to define that form of pancreatitis which is associated with diabetes mellitus. Interlobular pancreatitis, which spares the islands of Langerhans, is accompanied by diabetes mellitus only when it is so far advanced that the islands of Langerhans are finally altered, in common with the greater part of the secreting parenchyma. In a previous report I have described 21 cases of interlobular pancreatitis, in only one of which was diabetes present. In this case diabetes mellitus on the one hand was of mild type and glycosuria had disappeared when the patient was given a diet poor in carbohydrates, while on the other hand interlobular pancreatitis was so far advanced that the islands of Langerhans were surrounded and compressed by dense fibrous tissue. In six additional cases which I have re-

cently observed, interlobular pancreatitis has been unaccompanied by diabetes.

Interacinar pancreatitis, on the contrary, invades the islands of Langerhans and is accompanied by diabetes mellitus unless the lesion is of only very slight severity. In seven of nine cases which I have previously reported diabetes mellitus has been present.

Convincing evidence that the islands of Langerhans exert that influence upon carbohydrate metabolism, which heretofore has been attributed to the pancreas as a whole is furnished by a series of six cases in which the islands of Langerhans have been the seat of a peculiar hyaline change, wholly or partly destroying their cells. In all of these cases diabetes mellitus of variable severity had been present. In four instances interacinar pancreatitis was associated with the lesion, but in two cases the secreting parenchyma exhibited no noteworthy change, while the islands of Langerhans were in large part destroyed. The lesion has served the purpose of an accurately performed experiment selecting and destroying these structures which are embedded here and there in the parenchyma and in consequence of this lesion has occurred the same disturbance of carbohydrate metabolism which follows extirpation of the entire pancreas in the lower animals.

I have limited myself to a consideration of the cases which have come under my own observation. The conclusions, however, have been recently confirmed by a considerable number of observers who have studied changes in the pancreas associated with diabetes mellitus. Cases of diabetes accompanied by well-marked lesions of the ductless islands of Langerhans have been described by Wright and Joslin, Herzog and Steel, Gentis, Ssobolew, Weichselbaum and Stengl, Schmidt, Curtis, and Finney.

It must be borne in mind, however, that diabetes mellitus may occur without any demonstrable change in the pancreas. In a fairly large proportion of cases, constituting at least a third, the organ is found by gross and microscopical examination to be normal. Indeed, this fact is not surprising when we recall the complexity of sugar metabolism and the variety of factors which influence it. Experimental observations have demonstrated that temporary glycosuria may be produced by various injuries inflicted upon the central nervous system, notably by Claude Bernard's puncture of the floor of the fourth ventricle. Temporary glycosuria, it is well known, may be caused by the administration of the glucoside phloridzin which apparently so acts on the kidneys that they excrete part of the sugar that is normally present in the blood. Such facts do not explain the occurrence of human diabetes without lesion of the pancreas, but serve, nevertheless, to indicate that changes other than those which affect the organ may cause a disturbance of carbohydrate metabolism.

Of great significance are the observations of Cohnheim to which reference has already been made; outside the body disintegration of sugar cannot be brought about by the action of pancreatic substance, but when the expressed juice of pancreatic tissue is combined with that derived from muscle, the two in combination can cause glycolysis. If these results be accepted, it is not hard to believe that the disturbance of carbohydrate assimilation which is associated with diabetes may result from conditions which affect the muscular system even though the pancreas remain normal.

The relation of diabetes mellitus to lesions of the pancreas explains, I believe, the frequent association of diabetes with certain other diseases. It has long been known that cirrhosis of the liver is not uncommonly accompanied by diabetes mellitus so that diabetes with cirrhosis has been described as a special type of the disease. Among 280 cases of diabetes observed by Naunyn 29 were with cirrhosis of the liver, a proportion of one in ten. A considerable number of observers have noted the coexistence of cirrhosis and chronic interstitial pancreatitis, and in some of these cases diabetes mellitus has been present during life. Doubtless these lesions of the two organs may be dependent upon the same etiological factor and in several instances the individuals affected have given a history of excessive use of alcohol. Two cases of diabetes with cirrhosis of the atrophic type of Laennec have clearly defined for me the relationship of these two lesions, for in both instances chronic interstitial pancreatitis was present and was of the interacinar type, the islands of Langerhans being implicated in the sclerotic process. Through the kindness of Dr. Libman of this city I have had the opportunity of examining the pancreas from a third case of diabetes with cirrhosis and here too the organ has been found to be the seat of interacinar inflammation.

The remarkable condition known as bronzed diabetes offers an excellent illustration of the coexistence of cirrhosis and chronic pancreatitis in association with diabetes mellitus. The deposition of an iron containing pigment in the liver, pancreas and other glands is accompanied by chronic interstitial inflammation of these organs, and is associated with bronzing of the skin, and in the later stages of the diseases, with diabetes mellitus which is in such cases the usual cause of death. This rare condition has been designated bronzed diabetes particularly by French writers who have described the greater number of reported cases. I have studied and described an example of this condition of pigmentary degeneration; the pancreas was the seat of the interacinar type of pancreatitis. The lesion was, however, little advanced, and the patient who died with typhoid fever, had not apparently suffered with diabetes. Beattie has recently reported a case of bronzed diabetes in which the pancreas was the seat of chronic inflammation implicating the islands of Langerhans.

The following conclusion based upon the facts

just cited is, I believe, justified: When diabetes mellitus is found in an individual suffering with cirrhosis of the liver, the former disease is dependent upon the coexistence of chronic interacinar pancreatitis, doubtless produced by the same etiological factor, in some cases alcoholic excesses, which is responsible for the hepatic disease. In these cases at least it is possible to make a diagnosis of pancreatic diabetes.

In another group of cases, not inconsiderable in number, diabetes is associated with advanced arterial sclerosis. The frequent coexistence of the two conditions is not surprising since both occur more frequently with advanced age and in many cases, particularly where arterial disease is slight, their coexistence is probably accidental. Cases of chronic interstitial pancreatitis with arterial sclerosis have been described by several writers and in three of nineteen cases of diabetes, which I have described, degenerative changes were recognizable in the small arteries of the pancreas. In one case in which death occurred with gangrene of the leg, due in part at least to calcification and occlusion of arteries, the pancreas was the seat of chronic interacinar inflammation causing changes in the islands of Langerhans. I have recently seen at autopsy a similar case in which the arteries of the gland exhibited well-marked obliterative endarteritis. The occurrence of chronic pancreatitis in association with advanced general arterial sclerosis has this significance: When during life diabetes accompanies advanced arterial disease, it may with much probability be referred to chronic interacinar pancreatitis.

Lancereaux, more than twenty-five years ago, attempted to define clinically two types of diabetes: diabetes with emaciation due to disease of the pancreas and diabetes with obesity unaccompanied by lesion of the organ. Few clinicians have accepted the criteria proposed by Lancereaux and the existence of pancreatic disease is rarely established unless an autopsy is performed. In a few cases diabetes is associated with some lesion which causes such advanced destruction of the secreting elements of the gland that digestion suffers and fat or undigested proteids are readily recognizable in the feces. In these cases pancreatic disease is usually the result of longstanding occlusion of the pancreatic duct, causing injury to all elements of the organ, or to carcinoma invading and destroying it. In other cases, as I have just pointed out, associated cirrhosis of the liver or advanced general arterial sclerosis may give indication that the pancreas is at fault. In a large proportion of cases, however, it will be impossible with our present knowledge to decide during life if diabetes is referable to a lesion of the pancreas.

Even if in every case of diabetes mellitus it were possible to accurately determine the relation of the disease to the pancreas, the application of this knowledge to the treatment of the case would not at present be clear. For a few diseases a specific method of treatment has been deduced from a knowledge of etiology and pathogenesis. As an example of this logical sequence may be cited myxedema, a disease in some respects analogous to diabetes mellitus. When it had been established that the disease was due to impaired activity of the thyroid gland, a remedy was found in the thyroid tissue or its extracts obtained from lower animals, since the necessary internal secretion of the gland can be replaced by thyroid extracts administered by mouth or injected into the subcutaneous tissue.

Since the pancreas furnishes to the blood a so-called internal secretion, perhaps a ferment, necessary to normal carbohydrate metabolism, and since diabetes mellitus results when the pancreas is no longer capable of supplying this need, the possibility of artificially replacing the defect has suggested itself. A number of observers, among them Minkowski, found that fresh pancreas or extracts derived from it administered to dogs deprived of their pancreas failed to prevent glycosuria or to diminish its severity when established. No greater success has followed the administration of pancreatic tissue or its extracts to patients suffering with diabetes mellitus, and a considerable number of careful observers have failed to discover any noteworthy effect upon the amount of sugar excreted by diabetics subjected to such treatment. There is, however, some clinical and experimental evidence to show that when diabetes is the result of a destructive lesion which inhibits the digestive function of the pancreas, some benefit may be obtained by supplying to the intestine pancreatic ferments. A remarkable case described years ago by Fles has been frequently quoted. Diabetes mellitus was accompanied by disturbed digestion, abundant fat and undigested muscle fibers being recognizable in the feces. A watery extract made from the entire pancreas of a calf was daily divided into three parts and one part was administered after each meal. Though the patient continued upon a diet of bacon and fat meats, fat disappeared from the feces at the end of two days, but glycosuria persisted unchanged. Whenever the administration of the extract was discontinued, fat and undigested muscle fibers reappeared in the feces. The general condition of the patient was improved for a time, but death finally occurred as a result of phthisis. Autopsy showed that the pancreas was the seat of very advanced sclerosis. In a somewhat similar case Oser administered pancreatin with good result.

Recent observations of Cohnheim upon the glycolytic power of pancreas and muscle in combination suggest new possibilities concerning the nature of diabetes mellitus and may finally explain the failure to supply with pancreatic extracts deficiency of the internal function of the pancreas. Few diseases have been the subject of more careful experimental and clinical study and we are in possession of many important facts concerning the pathology and chemistry of diabetes mellitus. Still more accurate knowledge will doubtless find far reaching application.

THE PROPHYLAXIS AND MEDICAL TREATMENT OF DISEASES OF THE PANCREAS.[1]

BY GLENTWORTH R. BUTLER, M.D.,
OF BROOKLYN, N. Y.

The subjects assigned for this paper are the prophylaxis and the medical treatment of diseases of the pancreas. These topics are at first glance of an alluring interest. But the results of investigation and sober second thought are distinctly suggestive of certain chapters of a work which was written many years ago by a simple-minded and ingenuous student of nature. This book was entitled "The Natural History of Iceland." The seventy-second chapter consists of one sentence, which reads thus: "There are no snakes to be met with throughout the whole island." The forty-second chapter is even more direct, succinct, and informing. It says, "There are no owls of any kind in the whole island."

Prophylaxis.—The attempted prevention of diseases of the pancreas lies in an appreciation of their causes. Among the etiological factors assigned are syphilis, tuberculosis, arteriosclerosis, alcoholism, cardiac, pulmonary, and renal disease, acute and chronic infections, obesity, diabetes (not of pancreatic origin), neoplasms in close proximity to the pancreas, catarrhal and bacterial diseases of the intestine, and affections of the liver and gall-bladder (especially cholelithiasis). If therefore one or more of the conditions just rehearsed are capable of successful treatment, as may be the case, *e.g.*, syphilis, or surgical removal of gall-stones, by so much is the liability to pancreatic disease lessened or terminated. Beyond this we cannot, at present, go.

Medical Treatment.—Pancreatic disease is probably by no means of such infrequent occurrence as we commonly suppose. Nevertheless, owing to the great difficulties of diagnosis, its existence is rarely recognized *intra vitam*. The great majority of cases of disease of the pancreas recover or die without a correct and certain determination of their nature having been made. Naturally, therefore, medical treatment addressed directly to the diseased organ, even were it possible, is seldom practised. This paper does not, of course, deal with the question of surgical interference, which has afforded some brilliant successes.

Various remedies have been used with reported good results, but the correctness of the diagnosis in each case is open to doubt. Thus in chronic pancreatitis iron, nitro-muriatic acid, chlorine, calomel, and corrosive sublimate have been put forth as efficacious remedies. Much work has been done in the line of organic therapeutics, especially in cases of supposed pancreatic diabetes, by the administration in various ways, of the pancreas and its preparations. Some of these methods are the giving by the mouth of pancreatin, or the expressed juice, or the extract of the finely ground fresh pancreas of the calf or sheep, made with water, physiological salt solution, or glycerin, or the eating of the raw minced or slightly broiled pancreas, or taking it in capsules, or spread upon bread. The juice of the gland, and the minced gland macerated in an alkaline salt solution, have been given by enema. The expressed juice and the glycerin extract have been administered subcutaneously. The immediate implantation of the pancreas from a just killed sheep has also been undertaken, the patient dying in coma.

The practical results of pancreas-therapy have been disappointing in that disease of the organ has not been modified. On the other hand, when the disease is one which causes a lack of pancreatic juice, the use of efficient pancreatic preparations has in some cases measurably improved the digestion of fats and proteids. The internal use of ox-gall has also distinctly assisted the assimilation of fats.

In the present state of therapeutics the medical treatment of pancreatic disease is confined to the relief of symptoms, *e.g.*, pain, or jaundice, by the usual methods; and the maintenance of the strength of the patient by rest, careful feeding, and other commonly employed means, in order that he may survive the course of the disease or be better able to cope with the strain of an operation. When the presence of pancreatic calculi has been correctly diagnosed the injection of pilocarpine, which has been proved to increase the pancreatic secretion, should be practised, one successful case having been reported from Eichhorst's clinic. We may, however, look forward hopefully to the results of such work as has been done by those who have preceded, or will follow, me to-night, for these brief remarks form simply a bare condensation of the labors of many patient and splendid workers in a most interesting field.

THE CLASSIFICATION AND SYMPTOMATOLOGY OF DISEASES OF THE PANCREAS.[1]

BY CHARLES G. STOCKTON, M.D.,
OF BUFFALO, N. Y.

The classification of diseases, always difficult and usually unsatisfactory, is especially so as relates to the pancreas. This in part is because our knowledge of the pathology is incomplete and in part because the pancreas secretes certain enzymes or other active principles which, in the presence of disease, lead to peculiar and remarkable changes both in function and in structure, so that it is difficult to apply the stereotyped terms of classification.

Tumors of the pancreas occur as carcinomata of various forms, especially the dense, hard growths,—adenomata, tuberculosis, syphilis and cysts,—the last being divided into at least three varieties: retention cysts, proliferation cysts and hemorrhagic cysts. Much could be written on the symptomatology of these affections, but it must be passed at this time.

[1] Read at a symposium before the Medical Association of Greater New York, Feb. 8, 1904.

The so-called inflammatory diseases of the pancreas at once involve us in difficulty. Chronic pancreatitis is usually described as indurative, although fatty degeneration and ingrowth of adipose tissue often form a considerable part of the mass. Under the heading of chronic indurative pancreatitis we have to do with the degenerative processes, in some instances beginning with the blood vessels, in others with the duct of the gland, and in still others as the result of inflammatory processes reaching the pancreas from without. It may be a diffuse process involving the entire organ, or it may be confined to certain regions only. We have come to accept two forms of distribution of the fibroid degeneration, one the ordinary interlobular type, the other characterized by diffuse proliferation of the interacinar tissues which invades the islands of Langerhans and apparently constitutes the structural change upon which pancreatic diabetes depends. Especially in the interlobular pancreatitis there is marked hyperplasia of connective tissue, and the organ is sufficiently hard to make the term indurative quite appropriate, and when so is not infrequently mistaken for malignant growth. When the induration involves the head of the pancreas, it may, from pressure, obstruct the common bile duct and give rise to phenomena that suggest malignant growth, or cholelithiasis. If the choledochus escapes there may still ensue symptoms of more or less importance, depending upon interruption of the pancreatic function. If the disease invades the islands of Langerhans, we may encounter a persistent diabetes; but if these regions are spared in part or whole, nothing more than a transient glycosuria would be expected. The other symptoms are those of intestinal indigestion and, occasionally, fatty stools, lipuria, sialorrhea, emaciation, and in some instances severe anemia. Robson considers the diagnosis difficult, but this is not always so, as has been proven by operation and by autopsy. Given a palpable induration in the region of the pancreas, with disturbance in intestinal digestion, with, at times, traces of sugar and albumin in the urine, with or without increased salivation, fatty stools or lipuria and depreciation in general health without the cachexia of cancer, then one may make a provisional diagnosis of chronic indurative pancreatitis.

Robson and Moynihan dispose of the question of the classification of inflammatory diseases of the pancreas by dividing them into the acute, subacute and chronic forms. Fitz describes pancreatic hemorrhage, acute hemorrhagic pancreatitis, gangrenous pancreatitis and suppurative pancreatitis as well as the chronic forms. Oser speaks of acute hemorrhagic pancreatitis, suppurative pancreatitis, besides the chronic forms before alluded to. It does not seem to be satisfactory to attempt the explanation of acute pancreatic processes along the line of ordinary inflammation. It is true that the pancreas may become invaded by bacteria and, as a result, acute inflammatory processes develop, with hemorrhage, with necrosis, to which some apply the term gangrenous, usually accompanied by the fat necrosis of Balser. But while it is true that this results from ordinary inflammation of the pancreas consequent upon infection, we frequently find the same processes at work with entire absence of infection, the diseased tissues proving sterile to carefully conducted culture methods. In some instances an inflammatory reaction is evident, in others it is entirely lacking. What is present in all cases is the escape of pancreatic secretion into the tissue, the consequent necrosis of the pancreas and surrounding parts, accompanied by hemorrhage, liquefaction necrosis, and fat necrosis. While it is admitted that these phenomena may be excited by an inflammation of the organ, we must not lose sight of the fact that there are cases free from infection, and inflammation, as we are in the habit of using that term. It would seem to me just as correct to speak of peptic ulcer of the stomach as a localized inflammation as to apply that term to those cases of necrosis of the pancreas under discussion. In short, it would seem that the term necrosis should be used insted of inflammation in describing certain instances of acute disease of the pancreas. One of the most significant facts is the presence of hemorrhage in these cases: it seems to be a very early as it is an important step of the morbid process. Just why the hemorrhage occurs is not so easily explained. Of course, some pathologic agency must induce the hemorrhage, but to hold that this is inflammation in all cases would appear to be pure assumption. The difficulty is increased by the fact that the non-infected cases and some of the infected ones may follow a course apparently identical. Some infections of the pancreas lead to pus formation, what is called suppurative pancreatitis, or abscess of the pancreas. Such a case follows a different course from that of the so-called hemorrhagic pancreatitis. In the latter, even with extensive destruction of the tissues of the pancreas as well as of the surrounding structures, so that there may occur the sequestration of the pancreas and the accumulation of a liter or more of liquefied tissue, no pus whatever is found. This remarkable state of affairs is quite unlike what happens in inflammation and is unparalleled in pathology.

The symptomatology of acute hemorrhagic pancreatitis and that of hemorrhage into the pancreas are very closely related. Indeed, as has been said, hemorrhage may be the first recognized step in the necrotic process. In the onset there is intense pain in the lower part of the epigastrium, manifestations of shock, generally nausea and vomiting. These symptoms may subside after a few hours, or continue for a few days, and then subside. Not infrequently the pain diminishes, but the prostration continues, vomiting recurs, cyanosis appears, the temperature is raised from one to three degrees, and the pulse becomes more frequent, small, feeble and compressible. The abdomen is slightly distended, and there is in-

creased resistance in the upper half of the abdomen, where the tenderness is usually considerable, sometimes very marked. The general appearance of the patient suggests a grave abdominal trouble which is more striking in some cases than in others. The bowels are usually somewhat sluggish, but lack the motor paresis of peritonitis. The symptoms are increased by movements of the body, and yet there is not the disinclination to change position which is seen in those suffering from peritonitis. Sometimes the vomiting is so persistent that obstruction of the bowels is suspected; at other times the tenderness and pain in the upper part of the abdomen is so marked that one becomes suspicious of perforation of the stomach, gall-bladder or intestine. In a few instances slight transient glycosuria appears and traces of albumin in the urine are to be expected. Patients may continue in this condition for several days, or even weeks. I have known recovery from an attack to take place, the patient succumbing to a second seizure, as verified post mortem. More often the process continues for a few days without marked change, when somewhat suddenly the prostation increases, the pulse becomes "running" and almost imperceptible, and death results apparently from abdominal shock. Sometimes the patient sinks into a stupor during the last twenty-four hours, in other cases intelligence continues until the end. I have seen cases that were mistaken for intestinal obstruction, perforation of the gall-bladder and appendicitis, and yet it would seem that those who have carefully studied one typical case there would be little danger of misunderstanding the nature of the disease on a second occasion.

Now, as to suppurative pancreatitis or pancreatic abscess, it must be understood that there is considerable variation of the symptoms in different cases. Where the suppuration is associated with hemorrhagic pancreatitis we must expect to find the symptoms of the latter to which are added those of septicemia. On the other hand, there are instances in which the manifestations are merely those of suppuration in the upper part of the abdomen, and the element of shock may be less marked than in the hemorrhagic form of the disease. For some reason the pancreas appears to tolerate better the presence of pus than it does the escape of pancreatic secretion into its tissues. It is hard to explain why the presence in the pancreas of certain infections or the entrance therein of bile (according to Opie), or a slight hemorrhage into its substance is capable of producing a rapid, extensive and fatal necrosis of the organ and surrounding parts, and yet that suppuration may continue for a considerable period, in some instances, without producing the phenomena of acute hemorrhagic pancreatitis; nevertheless, there exist abundant data to show that such is the case. It is therefore proper in classification to put down suppurative pancreatitis as a process separate and distinct from that of so-called acute hemorrhagic pancreatitis or necrosis.

In making this statement one should repeat this reservation, namely, that in a proportion of cases we find both purulent and hemorrhagic pancreatitis in the same case, excited apparently from the same cause and producing a group of symptoms that include those which relate to hemorrhage, necrosis and suppuration. Leucocytosis is to be expected in suppurative cases, but is inconspicuous or absent in those of other types. That singular phenomenon, the fat necrosis of Balser, occurs in most, but not all acute processes of the pancreas, whether suppurative, necrotic or inflammatory. Its precise relation to pancreatic diseases is not yet satisfactorily explained in spite of much excellent experimental work done on the subject. In fact there remains to be elucidated a number of important and intensely interesting questions in diseases of this organ.

RENAL DECAPSULATION FROM THE PATHOLOGIST'S POINT OF VIEW.[1]

BY JOSHUA M. VAN COTT, M.D.,

OF BROOKLYN, N. Y.;

PROFESSOR OF PATHOLOGY AND BACTERIOLOGY, LONG ISLAND COLLEGE HOSPITAL, PATHOLOGIST TO LONG ISLAND COLLEGE HOSPITAL; BROOKLYN HOSPITAL, KINGS CO. HOSPITAL, AND CONSULTING PATHOLOGIST, ST. JOHN'S HOSPITAL.

The operation of renal decapsulation for the palliative or curative treatment of chronic nephritis involves three fundamental propositions for consideration: (1) The nature of the renal circulation; (2) The modus operandi of the restitutio ad integrum in highly differentiated organs; (3) The etiology and pathology of the disease.

In order to establish the validity of such a procedure, it is necessary to show that stripping of the capsula propria, and adhesion of the capsula adiposa are competent to reinforce the cortical circulation, and, assuming this to be possible, that the new blood supply, in operation with the laws of regeneration will arrest degenerative changes in the cortex, and restore those areas in it, which have been destroyed during the progress of the disease. Furthermore, it must be demonstrated that those causes which are responsible for the disease will cease to affect the kidneys after the operation has been successfully performed. Otherwise, if it stands proven that, by virtue of the morphology of the intrinsic renal circulation the collateral blood supply may not be drawn upon for its reinforcement, and if it be shown that regeneration sensu-strictiori does not obtain in the renal cortex; and if, again, it be true that chronic nephritis is a local expression of a general condition, it will follow as a corollary of these facts that this operation is not only futile, but must be regarded as harmful.

The Renal Circulation.—The renal artery divides at the hilum of the kidney as a rule, into four or five branches, the distribution of which, in relation to the pelvis, is such that three-fourths of the blood supply is carried anteriorily while one-fourth runs posteriorily. The arteries are

[1] Read at the Annual Meeting of the Medical Society of the State of New York, Albany, Jan., 1904.

strictly end-arteries, and branches do not cross from either side to the other. Three branches enter the cortex of the kidney after supplying the tissues of the hilus, passing over and under the renal vein into Bertini's columns. From here they cross with repeated branchings to the boundary between the cortex and medulla, so that from usually two large arteries originate in the circumference of each pyramid fine arterial ramifications whose branches have no communication with each other. These are the arterial arcades. From the arterial arcades pass smaller arteries, usually at right angles with the arcades, into the cortex where, after dividing one or more times, they split into fine branches that course in perpendicular direction between the cortical fascicles, or lobules, toward the periphery of the cortex. These are the interlobular arteries, and are wholly concerned in supplying the Malpighian tufts, excepting a certain number which go to the medulla,—the arteriolæ rectæ veræ, and to the capsule,—rami capsulares. Each interlobular artery gives off in its entire length, from two, three or four sides, a large number of fine branchlets having arterial structure, and measuring 18—45μ in diameter, which either immediately, or after a single division penetrate the capsule of Bowman. These are the vasa afferentia. From the vas afferens, immediately after its entry into Bowman's capsule are given of numerous capillaries which pursue a tortuous course within the capsule, *but do not communicate with each other.* This is the glomerulus, and the individual loops measure 7 to 9μ in diameter. They finally coalesce to form another single vessel which emerges from the capsule of Bowman and is called the vas efferens. This vessel has the import, and partially the structure of an artery; and, after emerging from the capsule resolves into the renal capillary system, which is found in both the cortex and medulla. The vas efferens is 9—18μ in diameter, about half the size of the vas afferens. It forms two sets of capillaries (1) a rich network with an elongated mesh, whose capillaries range from 4.5—9—13μ in diameter, called the arterial capillaries. This plexus surrounds the medullary rays in the cortex, and is then confluent with (2) a network of wider capillaries with a roundish-cornered mesh 11—33μ that surrounds the convoluted tubules upon all sides, and is called the venous plexus. These vessels finally coalesce to form the venous roots. These relations are constant, excepting with those efferent vessels emerging from the Malpighian tufts found in the inner zone of the cortex, near the bases of the Malpighian pyramids. Here they are distinctly larger, 22—35μ, and stretch downward into the Malpighian pyramids, running parallel to the straight tubules, being designated as the arteriolæ rectæ spuriæ. They course with repeated divisions at acute angles to the papillæ, where they decreased in size to 9—22μ, and finally are distributed here and in the medulla, in the last location emptying either through their ends, or by small twigs into the capillaries of this region which measure 6—9μ and which from the long drawn nature of their meshwork, resemble the arterial capillaries with which they inosculate at the pyramidal bases, or around the medullary rays.

Quite in resemblance with the arteriolæ rectæ spuriæ which emanate from the vasa efferentia, are certain arterioles which spring either from the interlobular arteries, the arterial arcades, or from those vasa efferentia which lie close to the medulla in the cortex. These are the arteriolæ rectæ veræ already mentioned.

The renal vein commences in two places, *i.e.*, on the surface of the organ, and in the apices of the palillae. At the periphery of the cortex they originate from the capillary networks of the cortex as small venous roots, some of which regularly surround the single lobules, and form between these somewhat larger branches,—the venæ stellulæ verheynii; others, stretching out over several or many lobules assemble to make larger branches. Both varieties then progress downward into the cortex as venæ interlobulares, and course with the interlobular arteries between the lobules, being strengthened by receiving many other venous rootlets from the interior of the cortex, which are formed from the venous capillaries surrounding the convoluted tubules. They then pass at once, or through somewhat larger branches, at right angles into the larger veins, which latter are situated with the larger arteries in the neighborhood of the pyramids, are connected by anastomosis, and finally lead into large valveless veins, which emerge from the kidney in line with the arteries. Before entering the larger veins, they receive branches from the pyramidal veins,— venulæ rectæ — which originate from beautiful capillary networks surrounding the capillary ducts, and also in part from loops springing directly from the arteriolæ rectæ.

They become thicker as they ascend between the tubuli recti by receiving small branches; and, with the arteriolæ rectæ form large vascular bundles in the boundary layer of the pyramids. The veins of this bundle empty through a certain number of larger branches into the arched ramifications surrounding the pyramids. The venous plexuses in the surface of the papillæ are finally associated not only with the venulæ rectæ, but also with the veins of the renal calices, thus forming a sort of connecting link between the outer and inner veins.

Aside from the communication of arteries and veins by means of capillaries, it has been shown by E. Steinach[2] and others that, in the neighborhood of the vascular arcades and the renal capsule there is sometimes direct anastomosis by means of precapillary vessels, which have a diameter of 10—12μ and 20μ and are at times very short, at others quite long.

The vessels of the capsula propria originate in part from the renal artery before its entrance into the hilus, from the suprarenal, lumbar, and internal spermatic arteries, also the vessels of the ureter.

According to Koelliker,[1] certain of the arteriae interlobulares, after supplying the Malpighian tufts send branches into the capsule, which break up into a wide mesh of capillaries which communicate with the capsula adiposa.

The veins of the renal capsule are in communication with those of the surrounding organs, and in part with the portal system.

It is obvious from this description of the structure and distribution of the renal blood vessels, first, that the arteries are terminals, *i.e.,* that they have nowhere any direct communication with each other, the only possible communication being intermediate through the capillary systems; second, that all of the vessels vary systematically in diameter in definite locations,—a fact which must certainly have important bearing upon the nature of the blood pressure in the various divisions of the vessels, and the renal circulation as a whole; third, that, with the exception of a few interlobular arteries which penetrate the capsula propria, and a few capsular arteries which enter the cortex, the only communication between capsule and cortex is capillary.

It is further obvious, that obstruction to the renal artery in the main trunk, or any branch must result in arrest of blood supply in an area of the kidney corresponding to the distribution of the vessel obstructed; and that, assuming reestablishment of the circulation in this area through collateral vessels, the direction of the current must be reversed. Thus it will be seen that, under such conditions, the delicate parenchyma of the kidney is subjected to two grave insults, *i.e.,* first, loss of nutrition, second, alteration of pressure due to failure of the vis a tergo in the artery, and the reversal of current in vessels of widely varying diameter.

In this connection it is to be remarked, that the history of renal infarcation coincides exactly with what would be expected of such a circulation.

Since the classical researches of Virchow[3], Colnheim[4] and Litten,[5] upon thrombosis and embolism, and their effects upon tissues, it has become common knowledge that the regeneration of tissues in infarcted areas is per cicatrice. Whether the infarctions be hemorrhagic or oligemic, the final result is the same, *i.e.,* coagulation necrosis, organization of the necrosed area, cicatricial contraction of the organized tissue. Similar changes obtain in endarteritis obliterans, where terminal vessels are involved; and this condition is regularly present in arteriosclerotic nephritis, and the chronic diffuse indurative variety. In these kidneys the depressed cicatrices are resultant from stenosis of larger or smaller arteries, usually in the cortex, often in the medulla, which produce infarctions, corresponding in area to the district supplied by the vessel involved. Occasionally such an infarcted area receives a branch from the capsula artery, in which event, if the area be not too large, and the artery be of sufficient size, trophic conditions may be sustained for a time; but even here, in the majority of instances, there is a progressive tendency towards induration with final contraction of the area.

Over these depressed areas the capsule is often dense, and firmly adherent; so that when stripped off, considerable portions remain attached to the cicatrices, thus rendering them impenetrable to blood vessels.

Other structural changes are regularly found in those portions of the cortex which are not infarcted, such as tubular dilatation and retention cysts; so that any further loss of tissue through adhesion to the stripped capsule, which usually carries with it the extreme outer layer of the cortex, is to be regarded as highly injurious.

With these conditions at hand, can the restitutio ad integrum sensu strictiori occur in the renal cortex? Two things would be necessary to accomplish this (1) the collateral blood supply should be sufficient to restore the normal circulation, and, (2) that a highly differentiated organ such as the kidney could regenerate its component elements.

Litten's experiments show that the collateral circulation is not sufficient to restore the equilibrium; and the researches of Marchand,[6] and many others whom he quotes, prove that renal regeneration does not take place beyond a certain point. Litten conducted a series of experiments principally upon rabbits, whose kidneys closely resemble those of man, in which he ligated the renal artery alone, the renal vein, and both vessels together. He also describes in detail, and accurately, the renal circulation, including the collateral vessels. His description of the circulation coincides with that of Koelliker, quoted in this paper, and also of Brödel[7] in his valuable contribution on the subject in the *Johns Hopkins Bulletin,* 1901, in which he points out new facts of great importance to surgeons in operations on the kidney.

There is time for consideration only of some of the salient points in Litten's paper which bear upon the subject now under consideration. He found that when the parenchymatous elements in the convoluted tubules were deprived of their blood supply for a period lasting over two hours, they died, and did not regenerate. Talma[8] and Werra,[9] in later similar experiments, confirmed this observation, which is now generally accepted as a fact. It is important here because of its bearing upon decapsulation and renal regeneration. Litten also found that when either vein, artery, or both, were tied the kidney increased from one-third to three times its normal size, becoming more tense. On gross section two hyperemic zones were found,—one at the periphery of the cortex, the other in a narrow belt half in the cortex, half in the medulla. The cortical tissue between these two zones is paler.

He found that these congested zones were produced by the collateral vessels, which were sufficient in the capsule and hilum to carry the blood into the capillary plexuses, but not sufficient either in numbers or force of current to reestab-

lish the circulation, the result being that the capillaries in these zones were gradually dilated and gorged with blood, which, if the ligature remained long enough finally stagnated, with diapedesis of erythrocytes and parenchymatous degeneration. The vis a tergo being so slight the vessels become filled and cannot empty, so that stasis followed by hemorrhage, and coagulation necrosis result. This condition of the circulation also accounts for the increased size of the kidneys. Exactly the same phenomena obtain in renal infarction, the only difference being that they are restricted to the infarcted area.

Litten found that, when the artery, vein, and ureter were ligated and the capsule stripped, the kidney became neither congested nor enlarged, a matter of importance here, because it clearly shows that stripping of the capsule completely cuts off what little peripheral circulation is derived from the capsular arteries. The whole bearing of this will be apparent when the subject of regeneration is considered.

Summing up all the facts the conclusion is reached, that very little can be expected from the renal collateral circulation when the main supply of blood is compromised. As to renal regeneration, the elaborate researches of Marchand, Barth and others, prove that, where extensive destruction of the renal tissue occurs repair is imperfect and never to the degree of restoration of functional activity.

Perhaps the best description of the processes of repair in the kidney is that of A. Barth,[10] in the pathological institute at Marburg, quoted by Marchand in his elaborate work on the healing of wounds and transplantation of tissues. This investigator operated on guinea-pigs, rabbits and dogs. He resected large wedge-shaped pieces in the long axis of the kidneys and either coapted the cut surfaces with sutures, or left them slightly separated. Before examination of the kidneys they were injected with blue gelatin; and this was done at periods of from two to 102 days after the operation.

Quoting Marchand, he says: "The adhesion of the wound surfaces apposed by suture is accomplished as usual through a fine layer of fibrin. The deeper still separated wound-cavity is filled with coagulated blood, at the borders of which are gathered many leucocytes (two to twenty-four hours). In the same manner the capsular wound is closed with extravasation which also involves the parenchyma immediately surrounding the wound. Where the wound was not completely closed, the cavity thus formed was filled with blood, coagulated fibrin, and remains of necrotic parenchyma. The degenerative changes in the neighboring parenchyma begin with epithelial swelling, indistinctness of nuclei, filling of the lumina of the uriniferous tubules with a homogeneous mass, which progressively fuses with the dead epithelium. In the lumen of many tubules are gathered together with granular detritus, many leucocytes; others show fatty degeneration of the epithelial cells, while after two days mitosis appears in the better preserved cells. Necrosis of renal tissue in the neighborhood of the wound can spread to a considerable degree and assume distinctly the form of a wedge in consequence of severance of a larger ascending arterial branch. No changes are found in the remaining renal parenchyma. After four days, growth of connective tissue cells in the region of the wound is richer; they press into the coagulum filling the wound, and can be demonstrated in large numbers between the tubules of the borders of the wound as well as the capsule. The tubules in this district are in part filled with coagulum, but for the most part engaged in growth, and rich in mitoses, which latter are found in great numbers in the connective tissue—and endothelial cells. Later the mitosis grows progressively less. The actual process of healing is completed in from eight to eleven days; and is later followed by cicatricial contraction. In the cicatrix are found new-formed small tubules, which are in association with the straight and convoluted tubules of the neighborhood, but can have no functional significance. Occasionally the contraction stretches out over larger areas of the kidney, whose tubules contained in a deeper strata of the cortex show clearly widening and enlargement of the epithelial cells as well as of the glomeruli, *resembling the better preserved parts of a contracted kidney.* New formation of glomeruli was never observed."

"These investigations of Barth led him to the conclusion that regeneration of a functionally active renal parenchyma in the cicatrix does not occur, any more than restoration of a degenerated parenchyma by compensatory hypertrophy, or complete new formation as Tuffier,[11] or Kümmel[12] have claimed."

Ribbert[13] in the last edition of his general pathology adopts the same view of the nature of the process of renal regeneration.

Thus the second point is answered. It is clearly so, that the restitutio ad integrum never obtains in the kidney in the strict sense of the word, the repair always taking place in the usual way, *i.e.*, per cicatrice. So that, even assuming the possibility of renewing the renal circulation by substituting the capsula adiposa for the capsula propria, there is not the slightest warrant for assuming the occurrence of renal regeneration as a result.

Based upon pure reason, and the results of laboratory experiments, Dr. Edebohls' theory of the operation of renal decapsulation for either the cure or relief of chronic nephritis must fall—it cannot accomplish it.

As for the operation itself only certain immediate and remote results are conceivable. There is but one condition, in one variety of chronic nephritis which should logically be relieved by decapsulation, and that is the tension in a large white kidney. But even here any such relief is more than offset by the damage occasioned in the act of stripping the capsule.

The fact seems to have escaped notice, that

when the capsula propria is torn away the very vessels from which so much is expected in the renewal of the circulation are torn away also. They are forever and irrevocably gone; and it is a physical impossibility that the capsula adiposa should do anything in the way of vascular regeneration, excepting by the usual process of formation of capillary anastomosis; and as Brödel well remarks, the direction of the circulation in the capsula adiposa being away from the kidney but little could be expected from it, even if it were possible to regenerate or substitute arteries which should penetrate the cortex. Again it seems to be forgotten that, even assuming the most desirable results in renewal of the renal circulation by this operation, there must be inevitable death of considerable areas of the cortical parenchyma in its very important outer zone; for the reason that, as all authorities agree, the renal epithelia die in two hours after being deprived of their blood supply, and it requires at least four days for the production of new capillaries. Furthermore, in those kidneys where the capsule is adherent, stripping becomes really dangerous, because, as has already been remarked, in such kidneys what remains of the cortex is already compromised. The act of stripping not only damages these quasinormal areas by tearing off a portion of the outer zone, but, in the act of repair, with adhesion of the capsula adiposa to these denuded surfaces, new cicatrices are formed which in the end can only contract and increase the trouble. Finally it must be urged that this operation totally disregards the fundamental principles which are involved in chronic diffuse nephritis. Excepting in those cases where it is definitely shown that the renal disease is due to purely local causes, such as pressure, or obstruction of the circulation from stretching of the vessels, or other cause, this disease is merely a local expression of a general condition. It would be hard to find good authority for combating the view that chronic nephritis is caused either by some form of toxemia which is endogenous, or exogenous, and in the course of which toxemia the renal structures are irritated and finally degenerate, or by direct obstruction to the general circulation from cardiac disease.

Where a kidney has been dislocated, or pressed upon by some other structure, it is easy to see how good may be accomplished by anchoring the organ, or removing the obstruction; but it is inconceivable that any radical gain could come from increasing the flow of blood to the kidney whose very toxicity is assumed to be the cause of the structural changes in the organ. Much more must it be urged, that harm will result from an operation which establishes the locus minoris resistentiæ in a functionally very important tissue, and necessitates repair by a process which is in itself in the nature of a connective tissue hyperphasia, and which, under the toxemic influence must surely hasten the progress of the disease, rather than retard or cure it.

In conclusion it must be reiterated, that (1) on teleological grounds the renal circulation cannot be restored by decapsulation and substitution of the capsula adiposa. (2) No amount of restoration of renal circulation would restore the integrity of the cortex. (3) Chronic nephritis being a local expression of a general disease will yield only to such treatment as is calculated to cure the general disease; and here there can be hope only of arresting the progress of the renal degeneration. The diseased portions of the organ will never regenerate.

Last September a series of experiments was begun at the Hoagland Laboratory, under the auspices of the "Van Cott Fellowship" by myself and my colleague, Prof. Archibald Murray, the present Fellow, for the purpose of determining the effect of renal decapsulation upon normal kidneys, and also the relation of the renal collateral circulation to trophic conditions in the kidney. Cats were selected because of their high resistance to operative procedure. The operations were performed by myself, assisted by Drs. Murray and Fincke; and the work of preparing the kidneys for microscopic examination was conducted by Prof. Murray, whose faultless technic ensures accurate findings. Ether was the anesthetic employed. Under strict aseptic precautions the following operations were done:

1. The kidney was delivered through an incision in the back close to the vertebral column outside of the peritoneum. The capsule stripped, ablated, and the kidney returned through the incision which was then sutured.

2. The kidney was delivered in the same manner, and retained, after decapsulation, between the muscles and superficial integuments, for the purpose of gaining a larger capsular blood supply.

3. In both of these operations the artery alone, the vein alone, and both vessels together were ligated in secondary operations, time being allowed for the healing of the wounds of the primary operation.

4. The kidney was decapsulated, retained between the muscles and skin, and, before closure of the skin incision the cortex was deeply scarred in various areas with a Paquelin cautery at a dull red heat.

The time limit for this paper admits of only a brief résumé of the findings in these experiments. In general they agree with those of Litten. The collateral circulation was not sufficient to replace the direct circulation, even for mere trophic purposes.

In all of the operations a new thick capsule was formed, with capillary and *not* arterial anastomoses. All of the kidneys showed marked degeneration of the cortical epithelium, especially in the outer zone; and all of the new capsules showed a definite tendency to project fibrous tissue into the cortex. In the cauterized kidney the destroyed areas were replaced by cicatrices which blended with the capsule. Where vessels were ligated, the cortex presented the appearance of an early stage of coagulation necrosis.

One cat was in bad general condition at time

of operation. The kidney was simply decapsulated and returned to the abdominal cavity. It was large, and very pale. A month after the operation the animal was killed, and the kidney injected through the artery with carmine gelatine. The new capsule was found to be irregularly thick, and the injection showed only capillary anastomosis with the cortex. The cortex itself showed all the lesions of a large white kidney; and there was not the slightest evidence of any regeneration. On the contrary the tubules of the outer zone were in collapse and the epithelial cells in them completely broken down. Sixteen operations in all were done on eight cats, with the uniform result of positive injury to the normal kidney, and no benefit to the large white kidney.

These findings are in harmony with the conclusions of the paper. At a later date, a more detailed report of the results of the work done in the laboratory will be made.

In conclusion, the writer desires to express his sense of high appreciation of the earnest work and brilliant conception which led Dr. Edebohls to devise this operation and put it into practice; for, while he cannot approve of it as a procedure, it is nevertheless a tribute to the energy and faithfulness with which our American surgeons are pressing forward for the mark of the prize of their high calling, in their ceaseless efforts to relieve a suffering humanity.

CANCER OF THE INTESTINE.

BY J. G. SHERRILL, M.D.,
OF LOUISVILLE, KY.

My experience with several cases of secondary cancer of the intestine, and especially with two cases of primary carcinoma, specimens of which are here presented, has convinced me that many points of interest are connected with a study of this condition and it is for this reason that this subject has been selected for consideration.

The term cancer, as here applied, is to be understood as including all forms of maligant neoplasms which involve the intestinal tract. Tumors of the carcinomatous type occur with much greater frequency than do the sarcomata. While it is claimed that cancer rarely attacks the intestine primarily, yet a study of the literature for the past twenty years will show that it occurs much oftener than we have been led to believe; moreover, owing to the obscurity of the symptoms, many cases are entirely overlooked and many more are recognized but not reported. Hemmeter[1] mentions 69,083 autopsies including the collections of A. Zemann, Maydl, Müller and Nothnagel, with 5,796 carcinomata, 8.4 per cent. of the whole number. Of these carcinomata, 1,296 were of the intestine.

DeBovis[2] *(Revue de Chirurgie,* June, 1900) has collected 426 cases of cancer of the large bowel, and states that it occurs once in every 2,500 cases of illness, averages one for every 300 deaths in hospital statistics, attacks males more often than females, and is seldom seen in children. Hochenegg,[3] of Vienna, reported to the thirty-first German Medical Congress, 282 cancers of the intestine from his own experience. Nothnagel[4] found in the Wiener allgemeine Krankenhaus from 1882 to 1893, that of 2,125 autopsies upon cancer cases, 243 were of the bowel; of 243 sarcomata examined during the same period, only three involved the intestine. He quotes Müller, of Berne, who found during his experience at Berne that of 521 cancers, 41 of the intestine, and of 102 sarcomata there was but one of the gut, the ileum. Smoler in fifteen years (1883 to '98) out of 13,036 autopsies found 13 cases of primary sarcoma of the small intestine, or one in 1,000 deaths. These statistics show the great rarity of sarcoma of the intestine. With the exception of the rectum, sarcoma of the large intestine is still more rare than that of the small.

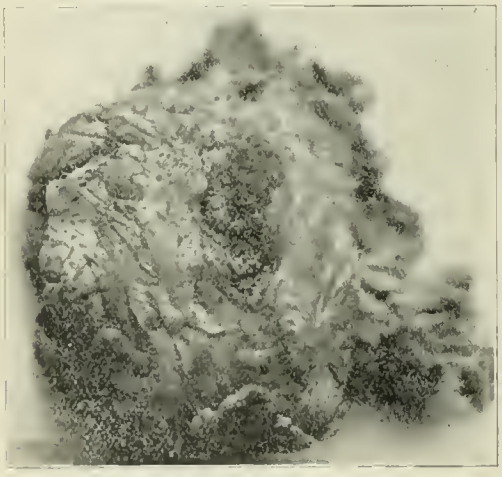
Still Libman[5] gives 59 cases of sarcoma of the small intestine; Jopson and White[6] have collected 22 cases of sarcoma of large intestine; Nothnagel reports 12 cases, Smoler[7] 13, Treves[8] 18, R. H. Harte[9] one case five years of age, and E. A. Robertson[10] has recorded a case of intestinal sarcoma in a child of four near the ileocecal valve.

With reference to the involvement of the different portions of the bowel the reports are not very complete. DeBovis[11] *(Revue de Chirurgie* 1900, Nos. 6 and 12.) gives carcinomata of the small gut 6.3 per cent., sigmoid 11.9 per cent., colon 20.4 per cent., rectum 49.2 per cent; this would leave 12.2 per cent. for cecum and appendix. Nothnagel's 12 cases of sarcoma show one to involve the duodenum, three the jejunum, four the ileum, three the cecum and one the rectum. Smoler's cases show seven in the ileum, three in the ileum and jejunum, and two in the cecum. The writers are all agreed that carcinoma attacks the large bowel with much greater frequency than the small, while sarcoma selects the small intestine and rarely involves the large gut. The appendix is also the seat of both carcinoma and sarcoma, although it occurs very rarely and is usually not recognized as a primary lesion, except by the microscope after the removal or autopsy.

E. Hurdon[12] reports (*Johns Hopkins Bulletin*, August, 1900) a case of primary carcinoma of the appendix, and mentions ten cases in literature of which only the three cases in which diagnosis had been made by the microscope, could be accepted.

Jessup[12] reports a case of carcinoma of the appendix and has collected 13 cases. Gifford[13] has noted a case of primary sarcoma of the appendix. A. V. Moschcowitz[14] presented a paper upon the subject of primary cancer of the appendix to the New York Academy of Medicine, March 5, 1903, and has studied the clinical picture from 16 reported cases, the majority of which, he says were reported after 1896. Dr. Weir, in discussion, reported a case of this condition which came under his observation in 1893 (See *Record* May 23, 1903). H. D. Rolleston[15] (*Lancet*, July 7, 1900) reports a case of primary carcinoma of the appendix occurring in a woman

Fig. 1.



Case I.—Dorsal surface of cecum showing site of fistula where carcinoma had ulcerated through gut.

aged twenty-six years. F. R. C. Whipham[16] (*Lancet*, February 2, 1901), reports a case of primary carcinoma of the appendix. Arthur W. Elting[17] reported to the Medical Society of the State of New York, January 28, 1903, three cases of primary carcinoma of the appendix which he had studied, and 40 cases, including his own, which he had collected from literature. He says that the condition was probably more common than would appear from the record, for in several cases the carcinoma had been only accidentally discovered at autopsy, so that many cases were doubtless overlooked. The disease showed a tendency to develop early but the symptomatology was exceedingly vague.

Men are more subject to carcinoma of the intestine than women. DeBovis gives proportion as 53.9 per cent. males, 46.1 per cent. females, 85 operative cases collected by Cumston and Vanderveer[18] give 63.83 per cent. as the percentage of males. The series of DeBovis is larger and it is probable that his percentage is more accurate.

Sarcoma as shown by Jopson and White in 22 cases involving the large bowel attacks both sexes with about the same frequency; of these, twelve were males and ten females.

Age.—Intestinal carcinoma, according to the DeBovis collection is most frequent from forty to sixty years. In 35 cases occurring from eleven to thirty years, 23 were in females. In 66 cases in the collection of Cumston and Vanderveer, the average is forty-two years—the youngest being nineteen and the oldest sixty-seven years, only eight are under thirty years. The ages of the sarcoma cases range from two to sixty-six years in Jopson and White's statistics, seven were under ten while only three were past forty years.

The variety of carcinoma most frequently met is perhaps the adenocarcinoma, although this point is not covered in many of the reports. Spheroidal-celled carcinoma either of the scirrhus or medullary type is also found. Squamous-celled carcinoma is rarely present except in the rectum, where it springs from the tissues near the anus. Colloid change is observed in some of the cases. The sarcomata most often assume the round-celled type. Fifty per cent. of the cases of Jopson and White were of this variety, 45 per cent. were lymphosarcomata and only five per cent. or one case, was of the spindle-celled variety. The adenocarcinomata rarely cause circular occlusion of the intestine, but this is the usual termination in scirrhus. Any form of malignant disease by infiltrating and matting the intestines together may interfere with the fecal flow.

Two cases of sarcoma are recorded in which a dilatation of the caliber of the intestine occurred. Ewald[19] mentions a case reported by Bessel-Hagen of a seven-year-old boy, in whom, during the course of an extensive sarcomatous infiltration of the jejunum, there had formed an aneurismlike dilatation of the size of a large man's fist. Jopson and White mention a similar condition in their case.

Not infrequently inflammation attacks the tissues around a malignant growth, and this is especially true in cases in which ulceration has begun. This was a prominent feature in my first case and from the number of reported cases simulating appendicitis, I conclude that it has occurred in some of these as well. A lymph-node taken from my case showed inflammatory changes but no cancerous infiltration. Metastasis from carcinoma of the gut seems to occur most often through the blood and the liver frequently suffers from secondary deposits.

Sarcoma, on the other hand, according to Jopson and White in 68.4 per cent. of the cases shows secondary involvement of the mesenteric glands, 26.3 per cent. of the peritoneum, 10.5 per cent. of the lung, 10.5 per cent. of the kidney, 10.5 per cent. of the spleen, 15.7 per cent. of the liver and 10.5 per cent. of other glands.

Tuberculosis is noted as a complication of cancer in a few cases. Invagination is a very frequent accompaniment of this condition in at least ten per cent. of the reported cases.

The cause of these growths is as little understood as that of cancer in any locality, and it is beyond the scope of this article to enter extensively into the discussion of the various theories offered to account for the abnormal cell growth which results in the production of these neoplasms. Among the various theories may be mentioned those of Cohnheim, Ribbert, and many others based on histogenesis. The questions of diet, heredity, traumatism and irritation have been well considered. The trend of recent opinion has been toward the parasitic explanation, the experiments of Schiller, Gaylord and others leading to this view, while the researches of the Harvard Cancer Commissions seem to disprove the claims that a parasite is the causative agent.

Personally, I incline to the parasitic explanation as the best so far offered, it having some weighty arguments in its favor, but consider it by no means proven.

The usual point of origin of these growths cannot be established from the present literature upon the subject. A frequent site is the follicles of Lieberkühn. Undoubtedly the primany carcinomatous growths must spring from the mucous membrane or its glands, and this view is borne out by the reported cases of carcinoma of the appendix, where the disease has been detected at its inception.

The following statements in support of this view are made in connection with H. D. Rolleston's case: "The facts that the growth was most extensive in the mucous coat, that it could be traced into the muscular coats, and that there was no growth in the peritoneum, showed that it originated in the mucous membrane of the appendix and was not a secondary growth, either implanted in the peritoneum or arising as a result of embolism within its substance."

Whipham's case also had its origin in the mucous coat. Jopson and White say that the point of origin in sarcomatous tumors is rather difficult to locate on account of the size of the tumor and the involvement of the bowel, when the subject presents itself to the operator or to the pathologist; but from the data of the microscopical examination of the tumors which they have been able to collect, and from the careful examination of their own cases, it seems to them that the mucosa is the starting point of these tumors and from the normal histology of the intestine, it will be the origin, if we take it for granted that they have their origin in the lymph follicles. The symptoms of either form of cancer affecting the intestine are very obscure, especially in the earlier stages when interference might offer some hope.

Some irregularity of the bowels may early be present but as a rule this is not of sufficient moment to demand attention. After a time uneasiness, discomfort or actual pain in the abdomen appears; owing to the gaseous accumulation this pain is often colicky in character, it is general over the whole abdomen at first, later it may become localized over the seat of the lesion and is often increased on motion. Although present in the majority of cases, the condition may exist for a long time before any appreciable pain is noticed. As the disease progresses tenderness will accompany the pain. If invagination develops as it does in some cases, the pain will become acute and the symptoms of that condition will be added.

Loss of flesh and strength is marked and progressive, greatly out of proportion to the discomfort of the patient, even when the appetite is good and the digestion appears to be normal. Any derangement of the digestion tends to accentuate the loss of strength, and nausea and vomiting may occur, especially if any tendency to constriction of the intestine is present.

Alternating constipation and diarrhea are often observed, being probably due to constriction of the gut, with impaction which after a time excites a diarrhea. When ulceration takes place the diarrhea may become continuous and prove very intractable, even exhausting the patient so that death results. Hemorrhage from the intestine does not often occur, in fact less frequently than we would naturally expect. It is most common in rectal cancers.

Many cases give a history resembling recurrent appendicitis, especially when involving the ileocecal coil; attacks of pain lasting a few days or weeks with tenderness, nausea, perhaps vomiting, tumefaction in some cases, and a slight elevation of temperature, with relief by treatment followed by a recurrence after a few weeks or months, are quite likely to be diagnosed as appendicitis.

My first case presented just such a history and other writers have mentioned this resemblance, notably Spellissy[20] who mentions cases reported by Janeway, Mühsam, Coley and McCosh, and C. N. Dowd[21] reports a case of annular carcinoma of the cecum which followed the usual course of a slowly progressive appendicitis. Eugene Smith also reports a case that had previously been mistaken for appendicitis. In Cumston and Vanderveer's collection eight cases simulated appendicitis, those of Caird, Mayo (2), Bernays, Lockwood, DeLaunay, Pilcher and Vanderveer. Libman reports five cases of sarcoma giving such symptoms.

The most constant symptoms of the disease are tumor which appears in every case lasting for any length of time, and a cachexia which gives this skin a peculiar yellowish cast. Anemia soon becomes marked and the patient is more and more debilitated until he dies of exhaustion, unless obstruction occurs and makes a rapid end of the case. Sometimes, however, the usual symptoms may be absent, and the first indication of the disease be the development of an intestinal obstruction in a supposedly healthy man. An interesting feature of two of the reported cases is the presence of tuberculosis with cancer.

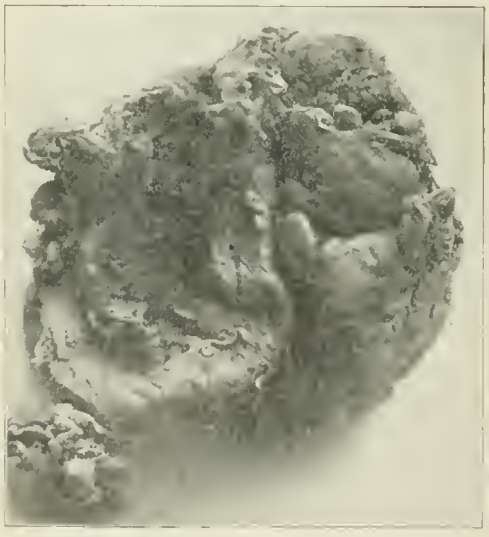
The duration of the disease is very uncertain, death has occurred in some cases in ten days after the first symptoms were noted while others have had symptoms for ten years.

The prognosis is very grave. Unfortunately treatment is usually applied so late that the results are not flattering. Therefore, an early diagnosis and operation will give these unfortunates the best chance, and we should not lose sight of the fact that such conditions are present with some degree of frequency.

Owing to the vague symptoms the diagnosis must largely be made by exclusion. Pain, tenderness, irregular diarrhea, alternating with constipation, dyspeptic symptoms, rapid loss of flesh and strength, even with good digestion, anemia, and cachexia, with an abdominal tumor will make the diagnosis. In the absence of tumor or some of the other symptoms an exploration is justifiable and may often be productive of great good.

Holländer and Löser[22] consider the formation of angiomata of the skin as suggestive of cancer, but this is probably of small diagnostic value, as is the enlargement of the cervical lymphatic glands mentioned by C. Tarchetti.[23] These glands are anatomically so remote from the intestines that they are unlikely to be involved until very late in this disease. The similarity between

Fig. 2.



Case I.—Anterior surface showing colon open and growth within.

appendicitis and intestinal cancer should call for special attention to this point in diagnosis.

The age of the patient is important, especially in making a differentiation between sarcoma and carcinoma. The rapidity of the growth is also important in this connection. Failing by the usual means of reaching a conclusion exploration is clearly indicated.

The treatment is to be largely determined by the extent of involvement. Resection of the intestine and extirpation of the growth offers the only hope of a permanent cure, and this chance though slight should be given the patient whenever practicable, as early in the course of the disease as possible.

Any of the classic methods may be employed. When this procedure is unsafe a fecal fistula may be established to relieve obstruction if present, or to remove irritation from the passage of feces over the diseased tissue. In some cases short circuiting of the diseased intestine by an anastomosis may be practiced with benefit; when the involvement is too extensive to permit operation, palliation is practically all that can be done, as visceral cancer has not responded to the Coley fluid, the X-rays, or to the injection of cancroin of Adamkiewicz.

Case I.—Patient, a white woman of twenty-six years, giving a history of repeated attacks of

Fig. 3.

Specimen from Case II.

what was thought to be appendicitis, came to operation February 17, 1903. At that time she presented a painful tender mass in the right iliac region accompanied by nausea, fever, and a rapid pulse. The abdominal wall was quite rigid. Upon opening the abdomen the mass was found to consist of the cecum and ascending colon which were matted together on their outer side. The peritoneum over this mass was thickened and the tissues around showed evidence of inflammatory changes, while the mesenteric glands were enlarged. Posteriorly a small abscess was found, which communicated with the lumen of the gut through a fistulous tract which had formed as a result of the ulceration of the neoplasm.

The growth extended through the wall of the cecum and colon, firmly uniting them. It appeared inside of the intestine as an irregular elevation about two inches in diameter, and quite firm in consistency. The small gut was not involved, the appendix was normal, and no other growth was discovered in the abdomen. A resection was the only thing possible under the circumstances and this was done by end-to-end suture, the dilatation of the ileum making this procedure comparatively easy. The patient rallied poorly and died 18 hours later from exhaus-

tion due to shock and sepsis. A microscopic examination showed the growth to be an adenocarcinoma. The mesenteric glands presented evidences of inflammation, but were free from malignant involvement.

Case II.—Man, white, age fifty-four years, came to me May 15, 1903, for relief from a fecal fistula which had persisted since the previous September. The fistula, according to his report, followed an operation done at that time for an abdominal trouble causing pain and fever. I found him very anemic, thin and feeble. Examination revealed a fistulous opening at a point half-way between Poupart's ligament and the margin of the ribs, and just external to the outer margin of the right rectus muscle. This fistula was surrounded by a nodular mass about the size of a small melon, which also involved the adjacent skin and muscular tissue. The mass could be isolated from the deeper tissues of the abdomen. A diagnosis of malignancy was very readily made and the patient fully informed of the gravity of the condition, and the slight probability of permanent benefit.

On May 16, 1903, this mass, which consisted of the cecum and ascending colon, a mass of omentum, a foot of ileum, and part of the abdominal wall, was removed and the ileum sutured to the transverse colon. The patient made a good recovery, but from the last report it is probable that he has a recurrence. The neoplasm was made up of a number of gelatinous nodules varying in size from that of a pea to that of an egg. These nodules looked like clumps of grains of cooked sago or rice, but were almost colorless or a pale grayish white, were very friable, readily separated from the mass and had very little vascular connection. One of these nodules was attached to the base of the appendix, which was distended at each end and constricted in the middle, and a number of isolated ones were removed from the peritoneum beneath the liver and on the posterior surface of the stomach. The microscopic examination showed the growth to be a cylindrical-celled carcinoma undergoing a mucoid or colloid change.

Sections taken from (*A*), the opening of the fistulous tract in the abdominal wall; (*B*), the body of the growth about the gut; and (*C*), one of the gelatinous nodules.

(*A*)—The histological findings at this point show the skin of the abdomen very much thickened, particularly the stratum Malphagii. The papillæ are irregular in size and shape, but there is no invasion of the subcutaneous tissue by the epidermal cells.

The connective tissue is infiltrated by small round cells.

The edges of the sections including the wall of the fistula shows an adenomatous growth composed of irregular branching tubules lined by several layers of columnar cells, irregular in size and shape, with nuclei staining lightly in some and deeply in others.

The general appearance of the glandular structure is not that of the intestine but more like the utricular glands of the uterus. As we go out into the tissue around the fistula these glands become dilated and filled with a homogeneous substance taking on a blue tint with the hematoxylin stain In some the walls are still lined with columnar cells; in others the cells are separated from the reticulum of connective tissue, and lie in the center of the space surrounded by the homogeneous substances in which is imbedded remnants of cells. As we get further away from the fistulous tract the adenomatous structure is entirely lost, and there is seen only the reticulum filled with homogeneous substance. The cells on the alveoli, where they are found in the center, show various degrees of mucoid degeneration.

(*B*).—The section from the body of the growth shows the same histological picture, with the exception that the more typical adenomatous structure is not seen, only the dilated alveoli as described above.

(*C*).—In the gelatinous nodules there is a thin capsule of connective tissue throwing off trabeculæ throughout the nodule forming irregular alveoli, none of which are lined by cells, but some are filled with the homogeneous substance alone and others have cells surrounded by this substance.[24]

FRACTURE OF THE BASE OF THE SKULL AS A CAUSE OF EPILEPSY: REPORT OF CASE.

BY CHARLES J. ALDRICH, M.D.,

OF CLEVELAND, OHIO;

LECTURER ON CLINICAL NEUROLOGY AND ANATOMY OF THE NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, CLEVELAND; NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND DISPENSARY; NEUROLOGIST TO THE CITY HOSPITAL.

THE following case of epilepsy, occurring in a magnificently developed and apparently healthy man, eleven years after a fracture of the base of the skull, is thought worthy of record. It is especially noteworthy, since epilepsy resulting from fracture of the base is indeed rare.

The case to be related also shows that the subject is entirely free from morbid hereditary predisposition. Moreover, he is remarkably without evidences of degeneracy; and is not only posi-

tively free from specific taint, but his epilepsy has developed beyond the so-called epileptic age. A casual search of the literature reveals but one other well-authenticated case of epilepsy caused by fracture of the base of the skull.[1] It is possible, however, that the absence of such observations is the result of one of those peculiar literary oversights which are not uncommon in medical literature, and when attention is once directed to the question, the report of other cases may follow.

These two cases, however, convince me that the statement of Pearce Bailey, "that fracture of the base does not appear in the causation of epilepsy,"[2] is unwarranted. In view of the fact that Dr. Bailey edited Golebiewski's *Atlas and Epitome of Diseases Caused by Accidents,* in which the other case mentioned is not only referred to but its history given, we would scarcely expect him to have made the former statement, nor to be the author of the following: "As convulsions play so minor a rôle in the acute symptoms of fracture at the base, we would hardly expect epilepsy to be a consequence of that injury, and it does not seem to be one."[3]

One cause for my belief that epilepsy results from fracture of the base more frequently than has heretofore been thought, resides in the curious fact that Bailey is the only authority, whom I can recall, who has published a study of the question, and is the author of specific statements in reference thereto.

The search of the literature which I have made establishes the fact that epilepsy is an infrequent sequel of basal fracture. The cause of this infrequency is probably owing to the fact that when the base is fractured the contiguous brain structures are the ones most likely to suffer. These are not structures whose injury is liable to result in convulsive disease, and fractures of the base where the lesions are severe, extending to the convexity, usually result in death.

The important fact that basal structures, even the basal cortex, do not seem to possess the convulsive elements of the convexity, is undoubtedly the explanation of the relative infrequency of epilepsy as a consequent or remote result of basal fracture. Yet from our knowledge of the irritating effects which may arise from injury to any portion of the brain, we are prepared to believe that cerebral injury wherever located may, in after years, result in epilepsy. Concussion of the brain, particularly in early life, is recognized as a not uncommon cause of epilepsy. Fracture of the base is an accident that usually occurs in adult life. It certainly cannot take place without concussion of the brain, and recognizing that concussion of the brain in the adult may produce epilepsy, we must, if we follow a logical course of reasoning, believe that fracture of the base will be far more liable to produce epilepsy than concussion alone.

The following case, which furnishes the text for this article, was observed through the courtesy of Dr. L. J. Smith, of Cleveland, Ohio: W. R., aged thirty-two years; occupation, polisher; married, and the father of two healthy children. His wife is healthy and has never had any miscarriages or stillbirths. His family history is exceptionally good. His father and mother are both living and in good health; there is no history of nervous taint or alcoholism either in the immediate or fairly remote branches of the family. He had but one brother, who was healthy, but died at the age of seventeen years of typhoid fever. His personal history reveals the fact that he never had need of a physician until his injury. I can also testify to this as a matter of personal knowledge, since I knew him as a healthy child and young adult. At the age of eighteen years he fell into the hold of a vessel, a distance of 12 feet, striking squarely upon his feet. He was picked up unconscious, when it was found that he was bleeding from the mouth, nose, and left ear. The vessel on which he was sailing "put into" Toledo, Ohio, and he was taken to St. Vincent's Hospital, where it was stated that he had suffered a fracture of the base of the skull. There were no marks or contusions on the body, thus rendering it certain that he struck squarely on his feet. At this time he weighed about 160 pounds. For a period of four weeks following his injury he was completely unconscious and at times quite delirious. After the disappearance of his delirium and unconsciousness, his mind appeared to be a perfect blank. He had forgotten everything, including his own name. His parents brought him to his home in Lorain, Ohio, where he was compelled to relearn practically everything. His speech was markedly affected; the character of this speech disturbance I have been unable to ascertain definitely.

He returned to sailing eight months after his injury, but did not appear to fully regain his faculties for over a year; in fact, some of his friends insist that he never has been quite the same since his injury. One year following his injury the captain of the vessel on which he was the mate states that he had some sort of a "spell" at night, in which he jerked and twitched and was unconscious. Eleven years later, in June 1899, he had what was then supposed to be his first epilepsy; but his friend the captain recently recalled the undoubted epilepsy which he suffered one year following the injury. In this last attack he bit his tongue and frothed at the mouth, presenting all of the classical characteristics of a major epileptic seizure.

In the same year, December 4, and again December 28, he suffered a severe convulsion. The following year he had one in February and one in December. In 1901 he had five convulsions. No minor seizures were observed except when he was taking the bromides.

His attack is not preceded by aura. His wife states that he appears to be irritable for several days preceding his epilepsy, and that during the seizure his eyes are turned to the right and upward. The face is also turned to the right with the chin over the right shoulder. The body is

then twisted around following, as it were, the eyes and head. This entrance into the tonic stage is usually without cry. The clonic spasms appear quickly, and are severe. After recovery from his attack he suffers only from general weakness and numbness, neither of which is localized.

Examination.—Patient is a large, handsome, blue-eyed man, weighing 190 pounds and is as perfect a type of physical manhood as one would wish to see. His head is large and well-shaped. He presents as few marks of physical degeneracy as any man I have ever examined. He is keenly intelligent, does not use either alcohol or tobacco, and is an artist of no mean pretensions. He possesses all of the attributes of a well-balanced man, both physically and mentally. His heart, lungs, and abdominal organs are perfectly healthy. The special senses are normal. He has never suffered from headache or dizziness except as a result of a recent attack. The deep reflexes are equal and perhaps slightly exaggerated; no ankle clonus, no jaw-jerk. His pupils are equal and symmetrical, and react promptly and normally to light and accommodation; palpebral apertures are equal; there is some nystagmoid twitching of the eyes while looking to the extreme right or left. The right disk appears to be slightly congested. The right angle of the mouth is somewhat lower than the left, and that side of the face appears to be slightly relaxed; when he whistles it is out of the left side, although by effort he can pucker the lips so as to whistle from the center of the mouth. The labionasal folds are equal. The labiomental crease is slightly deeper on the left than on the right side. There is no other evidence of paralysis, nor can I elicit any history of such disability.

In conclusion, it may be of interest to quote the brief report of the case of Golebiewski: A painter, twenty-nine years of age, who had frequently suffered from lead-poisoning, fell from a height of twenty-five feet on April 30, 1889. Lesion: fracture of the base of the skull with paralysis of the left arm. The patient was treated for one month in the hospital and for another month in the dispensary. He then resumed work. On September 4, 1889, he was again examined with reference to insurance, because of headache and dizziness. On November 11, 1889, he felt entirely well, and resumed work. He was then considered to be fully capable of self-support. On March 16, 1895, he suffered an epileptic attack, which was repeated at intervals. The connection between the accident and the epilepsy was proved, and he was allowed 100 per cent. insurance.

New Italian Hospital.—A hospital to provide for the wants of the Italian section of Philadelphia is to be established at Tenth and Christian streets. It is to be known as the Fabiana Italian Hospital.

MEDICAL PROGRESS.

MEDICINE.

Etiology of Chronic Habitual Constipation.—H. Lohrisch (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 5 and 6) explains the cause of many cases of chronic constipation as follows: An excessive absorption of the ingested food goes on in the intestines whereby the amount of dry residue in the feces is considerably diminished in the feces. The intestinal bacteria will find their culture medium deficient in nutritive principles and will not readily propagate so that much less indol, skatol, etc., are formed than under normal conditions. As these substances have the important physiological function of stimulating the intestinal musculature, less active contraction will occur where they are produced only in small amounts. It follows that in most cases of constipation the intestinal musculature may be in perfectly normal condition.

Infection of the Skin in Typhoid.—A mild type of furunculosis is very often observed in typhoid fever patients. A more severe type localized about the sacrum and buttocks was observed by D. L. Edsall (Univ. Penn. Med. Bull., March, 1904) in the wards of the hospital and which was apparently transmitted from patient to patient. The eruption began as a vesicular one and rapidly spread, becoming pustular. It did not seem to have any marked effect on the general condition of the patients. Cultures showed the presence of the *Staphylococcus aureus*. From the standpoint of the general clinician the chief interest in this series of cases lies in its relation to ward hygiene, and especially to certain details in nursing. In this case the infection was probably carried by attendants and utensils and when the proper precautions were adopted, the infection was checked. The infection here was evidently more virulent than that of ordinary furunculosis and during typhoid, patients are perhaps more liable to cutaneous infections than at other times.

Hydatid Cysts in Lungs and Heart.—The rarity of this condition makes the following case of interest, especially as it closely simulated pulmonary tuberculosis. R. H. Quill (Jour. Royal Army Med. Corps, April, 1904) reports the case with symptoms resembling phthisis pulmonalis. There was an almost complete absence, however, of the physical signs of that disease. Under hospital treatment the patient improved, but one evening was suddenly seized with intense dyspnea and went into collapse, which proved fatal. Autopsy showed numerous hydatid cysts in both lungs and in the right ventricle. In the latter were a number of loose cysts, one of which had evidently blocked the pulmonary artery and caused death. All the other organs were free. The case is a remarkable one. The origin of the infection was unknown—the patient had not been away from England and his previous health had been good.

Prognosis in Typhoid Fever.—The sudden appearance of one or other serious complication in what seems a mild and favorable case of typhoid fever, makes it necessary to always give a guarded prognosis. And to determine in what manner many of the different symptoms and complications are to be regarded, R. E. Sedgwick (Birmingh. Med. Rev., Feb., 1904) has made a study of 460 cases. His conclusions are: (1) Mild cases are commonest in the young, fatal complications likely in the old, therefore the younger the patient the more favorable the prognosis. (2) If onset is gradual, the case is likely to be mild; if onset is sudden, the case may be severe. (3) The amount of fever alone is not an important factor. (4) Sudden changes in the pulse suggest complications. (5) Early nervous symptoms indicate either a severe attack or lack of resist-

ance on the part of the patient. (6) Constipation is more favorable than diarrhea, and meteorism is unfavorable as it facilitates perforation. (7) Hemorrhage occurs chiefly in serious cases and the earlier it occurs the more serious it is. (8) Most of the complications tend to recovery; the most fatal being perforation, peritonitis and pneumonia. Among the complications were 24 cases of phlebitis, three of parotitis, three of tibial periostitis, one of periostitis of the sixth rib, one of arthritis of the shoulder, two of pleurisy with effusion, two of neuritis, one of necrosis of laryngeal cartilage with permanent tracheal opening. All of these recovered. One case occurred in a patient with Bright's disease, one with diabetes, and one with active pulmonary tuberculosis, but in none of these cases was the primary disease made worse by the typhoid. The case of tuberculosis was complicated by thrombosis of the left femoral vein, but recovered and actually gained weight during convalescence. Albuminous urine was found in 75 per cent. but had no relation to the severity of the disease.

Cardiac Dulness in Gastric Carcinoma.—Clinicians are still groping for the early signs and symptoms of this condition. W. Gordon (Lancet, April 9, 1904) believes that he has found a sign which, while not invariably accurate, seems to be present with sufficient constancy to render its recognition important. In conclusion, he states that great reduction or obliteration of the normal cardiac dulness is common in cases of carcinoma of the alimentary canal. This loss of cardiac dulness does not appear in the very earliest stages, but may precede cachexia and loss of weight. It is rarely observed in non-malignant cases, but rarely absent in the later stages. It does not seem to occur in cases of sarcomatosis. In doubtful cases, its presence is suggestive of carcinoma, its absence is slightly suggestive of the absence of carcinoma, if the symptoms under consideration have lasted for several months.

Iodide of Potassium in Lobar Pneumonia.—So very few specific remedies are at hand for disease that the claim which is urged for iodide of potassium as being practically a positive cure for pneumonia certainly deserves close investigation. H. Altschul (Med. Rec., March 26, 1904), during the past two years has treated 62 cases by this method without a death and over three times that number have been treated by his colleagues with similar results. The fact that he has given from 500 to 3,000 grains of this drug per day to these patients without untoward symptoms would certainly seem to indicate that the disease at least causes a special tolerance of the drug. In pointing out the applicability of this remedy to pneumonia he mentions the following important conditions which demand attention: (1) The toxemia; (2) the diminished respiratory surface of the lung; (3) the relative hypoleucocytosis with reduced alkalinity and increased viscosity of the blood; (4) the venous engorgement and laboring heart with a tendency to distention of the right heart; (5) the impaired action of the kidneys and glands; (6) the pyrexia and (7) the cough. He cites numerous authorities to show that when the iodides are given in these large doses there is a marked secretion of free iodide from the mucous membranes and that this has a marked germicidal effect upon the pneumococcus. A marked hyperleucocytosis is always considered a favorable sign in pneumonia and a hypoleucocytosis almost invariably means a fatal termination. The greatly increased activity of the lymphatic system and the great glands, following the use of the iodide of potassium is well recognized and is believed to assist in some degree in the causation of a hyperleucocytosis. Diminished alkalinity of the blood is believed by many to be an important factor in lessening the resisting power of the human body and this condition has been frequently demonstrated in severe cases of pneumonia and typhoid fever. For the purpose of alkalinizing the blood we know of no agent so effective as the potassium salts. Another important action of potassium iodide is its power to reduce arterial tension and thus relieve the burdens of the heart. The viscosity of the blood is also believed to be decreased, diuresis and diaphoresis increased. In analyzing the effect which this drug has upon the course of pneumonia it was found that in spite of the uniformly good results, the duration of the disease was not diminished and in none of the cases did the disease end by crisis. The temperature remained very moderate and the symptoms were markedly relieved. The potassium salt was used instead of the sodium because of its more rapid absorption and its greater alkalinizing power. When the diagnosis is made a dose of 10 to 15 grains is at once given and increased by 5 to 10 grains every two or three hours until defervescence is well established. However soft the pulse may be, the dosage is kept up, irrespective of the quantity, the only guide to the dosage being the regularity of the heart, and especially the character of the second pulmonic sound. Cardiac stimulants were seldom necessary, but strychnine and whisky were sometimes used. The iodide was given in a fifty per cent. solution with milk. A slight coryza and gastric disturbances appeared in a few cases but soon abated when the drug was still further increased. In a large number of cases from 1,000 to 1,500 grains were given in twenty-four hours without annoyance to the patients and the condition of the heart should be the sole guide to the amount that it is advisable to give.

Value of Leucocyte Counts During the Course of Typhoid Fever.—The value of the total and differential leucocyte count in the diagnosis of typhoid fever is very generally understood now, but the premonitory signs of complications which may be derived from frequent blood examinations do not seem to be fully appreciated. H. A. Higley (Med. Rec., March 26, 1904) reminds the profession that as the disease progresses toward the third and fourth weeks the relative number of mononuclears increases while the polynuclears decrease. If, therefore, frequent counts are made and an increase in the relative number of polynuclears is found, especially if a gradual increase in the total number of leucocytes is also observed, some complication should be strongly suspected. Numerous investigations of this nature have shown that the leucocyte count may arouse one's attention to the possibility of a complication at least twenty-four hours before other signs of a pneumonia, abscess or even perforation have developed. Furthermore, upon the appearance of a temperature late in the disease, a differential and total count is very helpful in deciding between a complication and a relapse.

OBSTETRICS AND GYNECOLOGY.

Tarnier's Principle of Forceps Rotation in Posterior Occiput Positions.—The mere engagement of the head at the inlet with the occiput posterior belongs to the initial stage of labor, says W. R. Wilson (Am. Jour. of Obstet., Jan., 1904). It foretells little of the future of labor and is usually only a temporary position. On the other hand, the fixation of the head in the cavity of the pelvis with the occiput directed to one or the other of the iliac joints means a condition of arrested labor which requires the application of forceps, as favorable delivery cannot usually be accomplished without artificial rotation. Theoretically the ideal application of forceps is that with the blades applied to the sides of the head with the concave borders directed toward the occiput. This latter condition per-

mits flexion to take place within the grasp of the instrument and establishes a parallelism between the longitudinal axis of the head and the long axis of the blades. But in posterior occiput cases there is no such symmetrical application of the forceps. The French writers teach that it is possible, while the head is transverse to apply the forceps to the head with one blade opposite to the sacrum, and the other opposite to the symphysis pubis, the concave border of the blades looking toward the occiput. Such an application will give the operator control of the head and permit him to rotate the occiput still further around until the latter comes under the symphysis. But practically, in the majority of cases, the oblique position of the head, where it can be overcome at all by manual deflection, is only changed temporarily. The classic application of the blades, say in an R.O.P., is equally disadvantageous. In the first place the desirable relation of the blades to the head is lacking. Secondly, owing to the imperfect flexion of the head in these cases, the forceps naturally grasp the sides of the head in a vertical direction with the points of the blades infringing upon the submastoid regions, thus increasing the danger to the child. Therefore, it would appear that practically the application in the transverse diameter is the most feasible—grasping the head in one or the other of the oblique diameters running between the frontal and parietal regions, according to the position of the head in the pelvis. Often the child's safety depends upon the rapidity with which the rotation is performed. Rotation may be delayed in difficult cases, owing to absence of molding and flexion. The head can by artificial rotation be carried out of its oblique position as it passes the bony outlet, and the mothers' interests are most favorably guarded. The vaginal wall may easily be caught by the edge of the blade and lacerated, or by forcibly twisting the blades the vagina may be drawn from its connective tissue base with a resulting separation of the surrounding muscles from their fascial attachments. A violation of the principles of rotation, as shown by Tarnier, means serious injury to the mother's soft parts. If rotation were attempted without regard to the principles, about to be described, the unhappy dilemma would arise of either injuring the pelvic floor by traction upon the widely separated blades in an oblique application to the head in an immovable position, or of injuring the vagina by improper rotation of the blades within it. The handles should be rotated in such a way as to permit the ends of the handles to describe a wide circle of revolution, leaving the tips of the blades as a fixed point. This procedure may be simplified by pressing the ends toward the side of the pelvis in a direction toward which the presenting part is to rotate without attempting to rotate the handles. A persistence in this lateral position of the handles will result in a gradual change in their position, yielding to the direction imparted to them by the altered position of the blades. Where such lateral pressure applied to the ends of the handles is apparently not effective, one of three possible influences prevents rotation: (1) The attempt at rotation has been made too early; (2) the head may be too large to undergo rotation; (3) the natural tendency may be for the occiput to rotate posteriorly, or in an opposite direction to that in which artificial rotation is attempted.

Recurrent Fibroids of the Uterus.—The subject of recurrent fibroids has been occupying the attention of gynecologists for some time past, inasmuch as the very nature of the pathology of the growth is not positively known, various observers considering it in different lights. V. S. Grousdeff (Roussky Vrach, No. 9, 1904) reports the case of a woman of forty-four years, who entered the hospital with a considerable hemorrhage and severe pain in the lower abdominal region. She was said to have been operated on two years ago. Bimanual examination elicited an enlarged, round immovable and painful uterus. The finger per opened os detects a soft smooth round body, which is easily turned about by the aid of forceps. The discharge is sanguineous with a slight odor of decomposition. Diagnosis of polypus was made; this was removed under chloroform by the aid of scissors and forceps, followed by a curettage of the uterus. Microscopical examination suggested an ordinary submucous uterine fibromyoma. The patient returned in about eleven months with a history of recurrent hemorrhage and pain (she having undergone in the interim another operation for the removal of a polypus) which caused the author to suspect a recurrent fibroid, but as a radical operation could not have been performed on account of the patient's exhausted condition, the growth was again removed and the uterine walls were vaporized. The radical operation (abdominal) was performed two months later. The uterus was freed from the adhesions to the surrounding organs, the vessels were ligated, and the uterus was removed entire. The uterus was greatly enlarged, and, with the enclosed tumor, weighed 1,020 grms. Microscopically the growth turned out to be a sarcoma, and the patient had to be operated on later on for generalized spindle-shaped sarcomata of several abdominal organs with a lethal issue. The question that the author raises is as to whether the growth was primarily a sarcoma or only a fibromyoma which degenerated into a malignant growth. He is inclined to consider it a primary sarcoma. As regards treatment of such cases the radical operation would seem indicated in all the cases of the so-called recurrent fibroids.

Metrorrhagia at Fourteen.—Instances of severe metrorrhagia in adolescents, at or about the commencement of menstruation are quite rare. The following case came under the observation of W. K. Walls (Brit. Jour. of Obst., Jan., 1904): Hilda P., aged thirteen years and four months had had four "periods" and for three months following these there was almost a continuous copious discharge. Occasionally it would be arrested for a day or a night. Treatment during this period consisted of rest in bed and cold diet. Various medicines were given, mostly of little avail; ergot seemed to increase the amount of discharge. Hot douches had no effect. Vaginal examination showed an enlarged cervix and considerable discharge. The external os was widely dilated, and the uterus antiflexed. Curettage was performed. Apart from these particulars there appeared to be nothing wrong with the uterus. The curetting was followed by gauze plugging, which was removed the next day, and the discharge continued to a slight degree for two weeks. For eight months following this the periods were normal. Though hemophilia is generally at the root of these cases, there was no evidence that it was the cause of the condition in this instance. Dr. Donald, who examined the tissue removed by the curette, found the endometrium characterized by a great amount of interglandular small-celled infiltration; the glands themselves were for the most part rather small, but here and there one or two of unusually large lumen; there was no increase of the vessels. It would appear that this condition resembled that found in metrorrhagia of certain adults and has been styled as "idiopathic endometritis."

Abdominal versus Vaginal Hysterectomy.—The decision whether to perform the ablation by one or the other of these two routes will depend in the early stages upon the particular predilection of the operator. John

B. Deaver (Am. Jour. of Obst., Jan., 1904) strongly opposes vaginal hysterectomy for cancer of the cervix uteri except in the presence of obstacles necessitating such a course, *i.e.*, a very stout abdomen, nephritis, or old age. The abdominal operation offers an increased space for necessary manipulation, greater security against hemorrhage and less risk of injuring the ureters, one is also better able to keep beyond the area of diseased tissue; a larger portion of the broad ligaments together with their lymph channels can be excised and the individual glandular enlargements noted and removed. Injury to the ureters is not so liable to happen because of the better exposure of these structures. In carcinomata uteri Deaver does not believe that it is necessary to dissect out the iliac glands, as the additional mortality from operation is not repaid by a lessened recurrence. Extension downward into the vaginal epithelium, forward into the bladder and backward into the rectum, is much more common than metastases into the iliac glands. Cancer of the body of the uterus requires complete hysterectomy and in the early stages the organ may be removed through the vagina.

The Beginning of Labor.—In attempting to explain the causes which bring the series of physiological acts that result in the expulsion of the fetus at the end of pregnancy, L. Blumenreich (Arch. f. Gyn., Vol. 71, No. 1) was led to make a number of exhaustive animal experiments. He sought especially to determine whether the gravid uterus responds more readily to stimuli than the organ when non-pregnant. In order to rule out spontaneous contractions of the uterus, the experimental animals were placed in a bath of warm saline solution. It was found that in the presence of an excess of carbonic acid or an insufficient supply of oxygen, the uterus of the gravid rabbits reacted much less strongly than that of the non-pregnant animals. The observations of Runge were confirmed, namely that lack of oxygen affords a more powerful stimulus to uterine contraction than an excess of carbonic acid. In not a single instance was it possible to bring on labor by respiration in CO_2. Mechanical irritation affords a much more marked stimulation to the gravid uterus, and moreover meets with a more ready response than in the non-pregnant organ. By means of mechanical irritation alone it was often possible to induce premature labor. These experiments seem to prove quite conclusively that mechanical influences play a much more important rôle in the induction of the labor act, than changes in the gaseous contents of the blood. If this be assumed, the probabilities are strengthened by the fact that these mechanical sources of irritation are increased from day to day by the increase in the volume of the gravid uterus.

The Experimental Production of Hydramnion.—The question of the origin of the liquor amnii still remains a much disputed one. A contribution to its solution is furnished by B. Wolff (Arch. f. Gyn., Vol. 71, No. 1) in an experimental research on the production of hydramnion. He first determined the normal amount of liquor amnii in rabbits at various periods of pregnancy and found that it increases up to the middle of pregnancy and then decreases in amount. If in a pregnant rabbit both kidneys are removed, it is found that no increase has taken place in the amniotic fluid of those fetuses which are in the first half of pregnancy, but a correspondingly greater increase is noted in nephrectomized animals the nearer full term is approached. In one instance the increase amounted to 21 times the normal quantity, which may with truth be called an artificial hydramnion. This increase cannot be ascribed to any transudation on the part of the mother, as nothing was present in the latter in the nature of an edema or ascites. It seems more likely, in the opinion of the author, that as a result of the extirpation of the kidneys, the urine elements which would otherwise have been excreted by the mother, have been transferred to the fetus and stimulated the kidneys of the latter to correspondingly greater activity. This also explains the fact that no increase takes place in the earlier part of the pregnancy, because here the function of the kidneys has not yet begun. By means of cryoscopic and comparative chemical researches the author hopes to further substantiate these claims.

Ethyl Chloride in Gynecology.—The advantages of this agent as a general anesthetic in this field are commented on by E. E. Montgomery and P. B. Bland (Jour. Am. Med. Ass'n, April 2, 1904). They claim that it is of especial value for administration to allay pain and relieve muscular spasm in abdominal pelvic examinations. Its employment will frequently permit of an accurate diagnosis in what would otherwise be an obscure case. The short time required for anesthesia, the rapidity with which the patient will recover from its effects, and the decreased tendency to nausea and vomiting, will allow its employment in office practice, with the assurance that the patient can return home without the need of prolonged attention. The same indications will lead to its employment in all operations of a minor character where prolonged anesthesia will not be required. In enfeebled patients requiring vaginal incision for pelvic drainage, it is ideal, for administration need not be begun until everything is prepared for incision, so that the patient will be under its influence only a few minutes. Probably its most effective employment will be as preliminary to the administration of other anesthetics. A nervous woman may be brought under the influence very quickly, without struggling, and convalescence from the final anesthetic is more rapid because she has not undergone any complete saturation with it. The principal disadvantages are that the patient passes under and out of its influence so quickly that the administrator must be unusually expert to avoid, on the one hand, profound anesthesia, and on the other, the emergence from its effects at an important stage of the operative procedure. The expense of the drug also precludes its use in a general clinic.

The Generative Cycle of Woman.—Ovulation with its attending sexual excitement is to the mammal what blossoming is to the plant, an evidence that an embryo seed is ready for impregnation. Among subhuman animals it is confined to distinct seasons and pregnancy and lactation follow always in due course. But in the human female, owing to more complicated conditions of life, pregnancy has not always followed ovulation, therefore ovulation has become more frequent, and menstruation has developed, menstruation being the depletion of a hyperemic, uterine mucous membrane which normally should have received an impregnated ovum. Hence every menstruation is the sign of a disappointed pregnancy, and is, therefore, an abnormal state. Such are the theories advanced by Jennie G. Drennan (Canadian Jour. of Med. and Surg., Jan., 1904), and she holds that if every woman had become pregnant when ovulation took place, as the lower animals do, menstruation would not have developed. But as civilization advanced mating became more difficult, the race more sexually inclined, because more pleasure-seeking, and woman, having less manual labor to perform, directed more attention to her sexual functions. She even, by her artificial life, cut down the period of lactation from the normal two or three years to eight or ten months, because the periodical hyperemia of the ovary began again that soon after pregnancy was completed, and, depriving the breasts of some of their blood-

supply, changed the quality of the milk. Unquestionably the sexual, social and religious life has been closely interwoven, and as mating became a more difficult matter, festivals became more frequent. In more primitive peoples religious feasts were really sexual orgies, and nowadays we find that those who are deprived of sexual relations find an outlet for their energies in various religious or philanthropic enterprises.

Central Paralyses of Pregnancy.—Paralysis during pregnancy of a hysterical nature is less frequent than generally assumed; in most cases R. v. Hosslin (Münch. med. Woch., March 8, 1904) found a definite organic basis. Genuine apoplexy is not uncommon immediately before, during and after parturition and is ascribed to hypertrophy of the heart, increased resistance in the vessels of the lower extremity and toxic influences which alter the vessel walls. As a rule the hemorrhage is very large and involves the central ganglia, lateral ventricles and internal capsules, so that the prognosis is very doubtful. The onset is sudden with coma, hemiplegia and paralysis of the facial and hypoglossal nerves. Another form of paralysis depends upon nephritis and is a manifestation of uremia; it generally occurs in primiparæ of advanced years and depends upon a circumscribed edema of the brain or upon hemorrhage. Prodromal symptoms such as headache, nausea, vomiting with or without edema and albuminuria are common and the paralysis generally sets in after one or more eclamptic seizures. On account of the deep coma the paralysis is often overlooked but may manifest itself as hemiplegia, monoplegia, hemianopsia or amaurosis; when dependent on edema it is often transient though the patient may still die after considerable improvement has set in. These cases are often wrongly looked upon as hysterical, since of such short duration. A large percentage of paralyses depends upon thrombosis of the cerebral vessels owing to puerperal infection or severe metorrhagia after birth or miscarriage. The onset is very gradual, consciousness is generally preserved and rapid improvement may follow. Convulsions frequently accompany the paralytic stroke, which is hemiplegic in type. The cause of cerebral embolism may rarely be a thrombus which is carried from a pelvic inflammation or a phlegmasia alba dolens, through an open foramen ovale into the cerebral circulation; in most cases, however, it is an ulcerous endocarditis during the puerperium. It is common for old valvular lesions to recur during pregnancy but endocarditis may also develop during this time, very insidiously with palpitation, dyspnea and a blowing, systolic murmur at the apex. The onset and course of the paralysis are similar to that depending on thrombosis. Rare conditions which cause paralysis are cerebral tumors, puerperal encephalitis, metastatic cerebral abscess after puerperal fever and progressive paralysis. Spinal lesions are of less importance, since most have already existed before and are hardly influenced by pregnancy. There is a distinct connection, however, between the latter and traumatic paraplegia and compression myelitis and occasionally a severe paraplegia will set in after copious hemorrhage. Less frequent conditions are meningomyelitis, spinal apoplexy, encephalomyelitis, acute and subacute polyomyelitis, multiple sclerosis and a chronic form of myelitis running the course of a spastic paraplegia; it is without doubt that any one of these diseases may develop during pregnancy in hitherto healthy women, so that the cause must be ascribed to some autointoxication. Both animal experiments and clinical experiences show that conception is not impossible when severe cerebral or spinal lesions are present. With cerebral disease, pregnancy usually runs its normal course if the life of the mother is not destroyed; with spinal disease, the patient is often unconscious of her condition and pregnancy may be interrupted when the disease sets in suddenly. Even parturition is hardly affected by cerebral paralysis and in the spinal forms the labor pains are usually of normal intensity. In many cases the delivery is easier and more rapid than in normal individuals.

A Rare Case of a Foreign Body in the Vagina.—Foreign bodies are introduced into the vagina with many aims in view—as curative means, for masturbation, for induction of abortion, etc. There are many cases on record of pessaries permitted to remain in the vagina for many years; though usually harmless, they may in some certain cases, induce considerable inconvenience and eventually injuries to the vaginal walls and in the neighboring organs. Orloff (Roussky Vrach, No. 11, 1904) reports the case of a woman of sixty years who was admitted to the clinic with pains in the lower abdomen and vagina, dyspnea, cough and purulent discharge from the vagina. After her second child she felt while at her work severe pains in the abdomen and a dragging down sensation, and to obtain relief she introduced into the vagina a croquet ball which she found in the garden. This was thirty years ago. This brought immediate relief, and during all these years there was no disturbance in the functions of either the bladder or the rectum. Examination elicited senile atrophy of the vagina at the introitus and higher up the finger struck a round, hard body. Neither the urethra nor the rectum seemed to any degree compressed. In view of the contracted introitus the foreign body could only be extracted piecemeal. Its substance remained unchanged, fresh and compact. The vaginal walls showed the presence of colpitis and here and there ulcerations. The patient left the clinic completely improved on the fifth day.

Hemorrhages from the Ovary.—The possibility that sufficient hemorrhage may take place from a corpus luteum which has undergone cystic degeneration, to really endanger life has only been proved in isolated cases. O. Burger (Zeitsch. f. Geb. und Gyn., Vol. 51, No. 2) believes that the case which he reports affords undoubted evidence of the cause of the bleeding and that there is definite symptom-complex which must be reckoned with, by which the condition can be diagnosed in those cases where it is possible to rule out a pregnancy. The patient, a woman of thirty-seven years, married nine years, but had never conceived. The menstrual history was normal and general health good. Her last period did not stop at the usual time but continued for three weeks, in slight amount. During this time she subjected herself to unusual exertion. She was suddenly seized with severe abdominal pains and vomited some blood. On admission to the hospital, a ruptured ectopic was diagnosed and laparotomy done. The abdomen was found full of blood, which apparently came from an ovarian tumor on the left side, the tubes being normal. The patient made a good recovery. The histological examination of the specimen showed a tendency in the ovary to a cystic degeneration of the Graafian follicles, certain of which had assumed considerable size while their walls had been very much thinned out. The presence of some pathological hyperemic condition caused a severe hemorrhage into the cavity which resulted in a rupture of the cyst wall, after which the blood entered the peritoneal cavity. The reason that no hematocele was formed may be explained by the fact that no inflammatory processes were present around the ovary. The continued bleeding during the three weeks may be ascribed to the constant hyperemia brought about by the woman's exertions during her menstrual period. The case is of considerable interest.

Loss of Blood During Labor.—More or less uncertainty still exists as to what shall be considered a normal amount of blood lost during a labor. From statistics relating to over 6,000 labors, F. Ahlfeld (Zeitsch. f. Geb. und Gyn., Vol. 51, No. 2) has deduced certain facts which he believes to be of practical value. It was only by the aid of a specially arranged bed that he was able to accurately estimate the exact quantity of blood lost in each case. In the middle of the mattress is an opening, accommodating a funnel which catches the blood and conducts it to a graduate placed under the bed. The blood is separately measured which comes away before the birth of the placenta, that which passes with the placenta, and lastly, that which is voided after the labor proper. Care is taken that the amniotic fluid and urine are carefully excluded. If at any time the amount of blood in the graduate exceeds 400 c.c., the attending physician is at once called. In the author's experience, the placenta is wont to remain in the vagina in the majority of cases, if the patient is not disturbed, from one and a half to two hours, and this he believes is the normal course. In 13 per cent. of cases, where the placenta was delivered spontaneously, a greater amount of blood (673 c.c. on an average) was lost than where the birth of the placenta was delayed. In estimating the influence of previous births on the amount of hemorrhage it was found that the increased amount was due rather to the increasing size of the children and their placentæ than to the number of previous labors. The length of the expulsive period did not seem to have any marked effect on the amount of blood lost. The most bleeding takes place during the first hour after the child is born. In pathological cases the same procedure was attempted, *i.e.*, to wait whenever possible with the expression of the placenta, for about two hours. In over 21 per cent. of the cases this period of waiting could not be adhered to, but the large number remaining shows that only for definite reasons, such as hemorrhage, should the third stage of labor be hastened. The after-effects of this loss of blood on the patient's condition are somewhat a relative matter. In normal, strong individuals, a loss of even 1,000 c.c. may not be followed by any evil consequences. For weak or sick persons no rule can be formulated. Where 1,500 to 2,000 c.c. are lost, it was found that in the majority of cases only slight or moderate degrees of anemia resulted. When the amount lost exceeds these figures, the result depends more or less on the patient's condition and whether the loss is sudden or gradual, four cases being reported where the woman lived even after having lost 3,000 c.c. In considering the after-effects of hemorrhage, the author believes that his statistics show that the danger of puerperal infection is increased in proportion to the amount of blood lost. The mother's ability to nurse does not appear to be very much affected, as about 50 per cent. of the breast-fed children reached their birth weight by the tenth day. It seems from these observations that healthy women can experience a considerable degree of hemorrhage during labor without being seriously influenced.

Gonorrhea in the Puerperium.—There is a considerable divergence of opinion as to the influence of gonorrhea on the puerperal state, some claiming that the disease has very little effect, others that considerable disturbance may be caused. A. Martin (Berl. klin. Woch., March 28, 1904) reports 13 cases of chronic gonorrhea which he kept under observation during their labor and puerperium. In none of these cases were any symptoms present which could be attributed directly to the venereal disease. In addition they seem to confirm the assumption that so-called chronic gonorrhea is no barrier to pregnancy, in most instances, even where there is a localization of the disease in the cervix or, as in one of the cases, there is present a gonorrheal salpingitis. In none of these patients did abortion come on. In 12 cases the labors were favorable, in one of which an acute exacerbation of the gonorrhea may have had some influence in hastening the labor by the rise of temperature. In the remaining case, extensive adhesions of the placenta delayed the third stage, but subsequent examination showed that this condition was not due to the gonococci. In four cases the puerperium was practically normal, in the remainder there was a rise of temperature, coming on rather late, and this the author considers a characteristic of gonorrheal infection. Involution moreover did not appear to be interfered with and no perimetritic involvement occurred such as has been noted in the acute cases. Although the author considers that the relation of gonorrhea to pregnancy must still furnish a doubtful prognosis, he does not agree with most authors who assume that it is "ad malem vergens." The treatment should be limited to local douching with normal salt solution, to which antiseptics may be added, but the most satisfactory results were obtained with applications of sterilized yeast both to the cervix and the urethra. Where gonorrhea is recognized as the cause of disease in the adnexa or the uterus, radical operations should be resorted to with caution, and the hope of spontaneous cure should not be abandoned too early. In isolated instances the severity of the complications must necessarily be taken as the guide; and where operation is called for, he considers that evacuation of the pus through the vagina forms the most satisfactory procedure.

Fetal Thyroid Hypertrophy with Maternal Eclampsia.—The following interesting case is reported by W. E. Fothergill (Brit. Jour. of Obst., Jan., 1904): Mrs. D., aged thirty-seven years, a short, stout woman, had had two early abortions and a third pregnancy. In eighteen months she again became pregnant but aborted at the third month. April 14, 1902, she became pregnant for the fifth time. On December 3, 1902, her urine was normal. Her thyroid became enlarged shortly after the inception of the pregnancy. On Dec. 7, she developed edema of hands and feet, and on Dec. 16 her urine contained 0.2 per cent. of albumin. On Dec. 27 she developed headache and vomiting, and later still, all the signs of a typical eclampsia. Under the proper treatment this cleared up; and on Jan. 1 she went into labor. A small female child was easily born; forceps being employed. It cried freely immediately, and some venous distention at the neck at once became visible. After the mother had received attention, the examination of the child revealed the presence of a large, solid tumor, representing the whole of the thyroid gland. This was covered by an enormously dilated venous plexus. The head and neck became more and more intensely congested, and it became clear that the circulation, as demanded by the pulmonary circulation, could not be established. The child died a few minutes later. For twenty-four hours after the completion of the labor there was complete anuria, but the temperature had been quite normal and the pulse-rate 140. Thyroid extract was given to the extent of 30 grains. Two days later the amount of urine voided was about five pints. On January 4 the pulse rate had fallen to 110, with good, large amounts of urine still being passed. During the next few days the patient's condition gradually became normal. The post mortem on the fetus showed the liver to be very large. The enlargement of the spleen appeared to be due to overgrowth of all the tissue elements, especially the glandular elements. Most examples of "congenital goiter" occur in "goiter districts," and in goiterous families. A form of enlargement of the

fetal thyroid may follow the administration of potassium chlorate to the mother under certain circumstances. In many cases of habitual abortion the administration of small doses of potassium chlorate is followed by the extension of pregnancy to its normal limits. Careful examination of the abortive ova expelled by these patients show that death is due to extensive thrombosis within the intervillous space. Large doses of potassium chlorate are well known to produce certain destructive changes in the blood, the therapeutic use of the substance having produced death in this way, especially in children. As to the occurrence of hypertrophy of the fetal thyroid, it may be argued that a toxic state of the maternal blood is to be blamed for this, and for abortions not prevented by the administrations of the potassium chlorate. It may also be argued that the hypertrophy of the thyroid was the direct result of changes in the maternal blood caused by potassium chlorate.

PHYSIOLOGY.

Complete Inversion of Viscera.—In visiting the autopsy room of the hospital M. K. LENTZ (Roussky Vrach, No. 9, 1904) came across the body of a woman of sixty years in whom the following transposition of viscera was found: the entire right lung was found on the left half of the chest, while the left lung was seen in the right chest. The heart was demonstrated on the right half of the chest; its left ventricle to the right and the right one to the left. In correspondence with the position of the ventricles, the aorta and the pulmonary veins issued from the right ventricle, while the pulmonary arteries and the vena cava originated from the left. The arch of the aorta was directed from left to right. From the innominate artery there branched out, instead of the right, the left carotid and subclavian arteries, while the right carotid and subclavian issued directly from the aorta. The descending aorta was placed to the right of the spine. The esophagus was found to the right of the spine. The liver was seen on the left, the spleen to the right, the left lobe of the liver was on the right side, and the right on the left. The stomach was transposed to the left of the median line, but its curvatures were normally situated, namely the large externally and the small internally, it thus seemed as if the stomach had been rotated 180° and then transported to the right half of the body; the gastric opening was found to the right and the pylorus to the left of the spine. The duodenum was turned with its convexity to the left, instead of the right as is normal. The head of the pancreas was found on the right, and its tail to the left, thus its head was toward the liver and its tail toward the spleen as in the normal relation to these organs. The ascending colon and the cecum with the appendix were placed in the left iliac region, with the descending and sigmoid to the right.

The Absorptive Capacities of the Skin.—It has long been thought that the power of many substances to traverse the skin from without inward, is very slight. SCHWENKENBRECHER (Arch. f. Anat. u. Physiol., Feb. 24, 1904) in a long series of experiments on mammals, finds that a large number of substances are readily absorbed by the skin. These are mostly soluble in water and oil and their absorption is dependent upon the osmotic laws that govern the cells in general. The experiments were conducted on white mice by immersing the animals in the respective solutions. The following were readily absorbed: ethyl alcohol in aqueous or oily solution, amyl alcohol, ethyl ether, chloroform, iodoform, iodether, cyanogen compounds, aldehydes (formaldehyde), chloral hydrate, ketones, phenol, lysol, resorcin, guaiacol, creosote, salicylic acid, anilin, antipyrin. As regards the alkaloids, the author found that strychnine nitrate is not absorbed by the normal skin. The same is true of basic strychnine. Nicotine is absorbed. The author cites Bouchut who found narcotic symptoms in children in whose skin opium had been placed, and Kunkel, who speaks of smugglers suffering from the toxic effects of nicotine absorbed from the tobacco hidden next to the skin.

Changes in the Blood after Muscular Exercise.—Healthy young men taking regular physical exercise have a normal blood count of 5,600,000 red blood cells and 8,800 leucocytes per cubic millimeter, the ratio being 1:636, according to P. B. HAWK (Am. Jour. Physiol., March 1, 1904). There is an immediate increase of reds and an accompanying leucocytosis after running, walking, bicycle riding and swimming. The immediate increase of the red cells is inversely proportional to the length of the exercise period. The leucocytosis is inconstant. The maximum average increase of 22.5 per cent. in the number of the red corpuscles is caused by the short swims, the greatest increase being secured after participation in water polo for three minutes. Long bicycle rides produce the minimum average increase of 9.7 per cent. As regards the leucocytes the maximum average increase followed the exertion incident to the long swims. Short swims produced the minimum average increase. The increase in the number of red corpuscles produced by muscular exertion is probably due primarily to the passage into the circulating blood of a large number of cells lying in various parts of the body and inactive before the time of the muscular exercise. The leucocytosis is due to the changed distribution of the leucocytes and their accumulation in the peripheral circulation.

Some Phenomena of Animal Pigmentation.—A field of physiological research, which has been vigorously tilled during the past few years and which promises practical results from the standpoint of the pathology of pigmented neoplasms, is the subject of the formation of animal pigments. R. C. SCHIEDT (Am. Jour. Physiol., March 1, 1904) reports the results of his interesting experiments in this line. He deprived oysters of one of their shells and exposed them to pure light, with the result that the animals secreted pigment over the whole of their body. The chemical or blue rays produce the same pigment, but not so with the red rays, which, however, protect the animal against the pathological changes due to irritation. The pigment is formed in the ectodermal organs of the epidermis, and in the organs of the mesoderm, as the heart it is embodied within the endothelium and connective tissue fibres. On placing the animal in darkness all pigment disappears. The author also finds that pigments produced under pathological conditions are not permanent, thus differing from the pigments formed under physiological influences. The author also believes that pigment granules are excretory products of protoplasm caused by pathogenic conditions, being reabsorbed when the conditions are removed. In this he agrees with Loeb. In the oyster the absence of the protective shell causes special irritation, perhaps a secretion of chromatin by the nucleus, and a restitution in darkness in which the animal is accustomed to dwell. This secretion is probably the result of a chemical process, as shown by the effect of the chemical or blue rays.

Contribution to the Physiology of the Thymus.—An investigation of the physiology of the thymus gland was made by D. N. PATON and A. GOODALL (Jour. of Physiol., March 29, 1904) with interesting results. In guinea-pigs the thymus continues to increase in size till the animal reaches a weight of about 300 grams, or an age of about two months, *i.e.*, at about the time when the animal becomes capable of reproduction, and after

that time it begins to degenerate. Removal of the thymus even on the day of birth has no influence on the growth of the animal. Removal of this organ causes no change in the number or character of the erythrocytes, but is accompanied by a decrease in the number of leucocytes, which, in the animals observed, lasted about two months. All varieties of leucocytes took part in this decrease. Thymusless animals which became pregnant showed a normal leucocytosis. Thymusless animals infected with tubercle showed the same increase or altered proportion of leucocytes as is manifested by animals with the gland intact. The injection of terebene caused a leucocytosis in thymusless as in normal animals. The injection of broth cultures of staphylococci and streptococci did not usually cause the marked leucocytosis in thymusless animals which it produced in normal guinea-pigs. The resistance to the toxins of streptococci and staphylococci is diminished by removal of the thymus, which removal, however, has no effect on the resistance of the animal to diphtheria toxin.

Distribution of Nitrogen in Urine.—The various nitrogenous principles in the urine of healthy individuals were determined by A. Landau (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 5 and 6) as follows: Total nitrogen was estimated according to Kjeldahl. A certain portion of the urine was then precipitated with phosphorvolfromic acid and the nitrogen determined in this precipitate: this corresponded to ammonia, the purin bodies, kreatinin and the pigments. The nitrogen of the filtrate gave the figures for urea and the amino-acids. The urea itself is best determined according to Schöndorff, the purin bodies after Camerer's method and ammonia according to Schlösing. The following average figures were obtained during health: Purin-nitrogen 1.01 per cent., ammonia-nitrogen 2.42 per cent., urea-nitrogen 90.87 per cent., amino-acid-nitrogen 2.89 per cent. The kind of ingested proteid seems to have little influence except that the amino-acids are rather high after meat and low after casein. The amount of amino-acids can also be increased by the ingestion of amino-acids such as asparaginic acid, but not if bicarbonate of soda was given at the same time. The only known amino-acid excreted with the urine is hippuric acid, but probably a number of other similar bodies are voided. Excessive or deficient nourishment seems to have no influence on the distribution of nitrogen in urine.

The Macrophagocytic Reactions of the Human Spleen.—There are present in the spleen, according to E. Gauckler (Jour. de Physiol., March 15, 1904), macrophagocytes whose function is that of erythrolysis and leucolysis, which are normal processes of the spleen. Any cause which leads to adulteration of the blood, particularly that which underlies icterus, exaggerates this macrophagocytosis. Beside the splenomegalies of infectious or congestive origin, there are forms attributed to the macrophagocytic reactions. These are the result of the excessive number of the macrophagocytes, or of the hypertrophic sclerosis of the organ induced by the excessive hemolytic reactions. The macrophagocytes produced in the spleen in excess pass by way of the blood-vessels to the liver. The relationship between splenomegaly and hepatitis may be a double one. Either the adulteration of the blood consequent upon a primary lesion of the liver produces hemolytic and sclerotic changes in the spleen, or else the adulteration of the blood is primary, and the secondary lesions in the liver are produced by the macrophagocytes brought there from the spleen.

Chemistry of Proteids.—Owing to their exceedingly complex composition, proteids alone have failed to yield to chemical analysis and much further work is necessary before a probable formula can be given. Some proteids have been very carefully studied so that almost all the molecules which enter into their composition are known; thus edestin yields no less than eighteen. It is, however, impossible to say how these radicals are joined together, whether in the form of an open or closed ring, a chain or both. A. Kossel and H. D. Dakin (Münch. med. Woch., March 29, 1904) have studied a group of proteids known as the protamines which may be looked upon as the least complex of these bodies. By the common analytical methods they can be split up into only five simpler bodies, viz., aminovalerianic acid, a-pyrrolidincarbonic acid, serin, urea and diaminovalerianic acid. The latter two are firmly united as a compound known as arginin. The proteolytic action of ferments is the same as that of hot acids since the same decomposition products result and this holds true for the simple protamines as well as for the more complex albumins of the higher animals. In many organs, however, an exceedingly active ferment, arginase, may be detected, which can do more than acids, even after prolonged action at boiling temperature, since it is able to split arginin readily into its two components. This action is due to the splitting up of an imide group by chemical union with water.

Experimental Toxic Leucocytosis.—A series of experiments to determine the effects produced in the blood of dogs by the intravenous injection of putrid horse serum, the relations existing between body temperature and leucocytosis and how changes in the walls of the blood vessels affected the latter, are published by J. G. Silverman (Univ. Penn. Med. Bull., March, 1904). It was found that the injection of putrid horse serum causes a primary hypoleucocytosis, in which the polymorphonuclear neutrophiles are diminished and the mononuclear elements increased, followed by a secondary hyperleucocytosis which is characterized by (*a*) a great increase in the polymorphonuclear variety; (*b*) an appearance of cells on the border line of myelocytes, as well as an actual presence, in the severe cases of leucocytosis, of mononuclear neutrophyles in small numbers; (*c*) a deficiency in hemoglobin which was found in 60 per cent. of the dogs experimented upon, associated with an appearance of normoblasts in the blood. There is no definite relation between the leucocytosis and the rise of temperature; the grade of the leucocytosis is not proportionate to the height of the temperature, and the maximum rise in one occurs independently of that of the other. Inhalations of amyl nitrite and injections of potassium nitrite cause a primary hyperleucocytosis in a very short time, due probably to the dilatation of the capillaries. Potassium nitrite administered before the injection of peptone lessens the duration and the extent of the disappearance in the number of the leucocytes during the hypoleucocytosis, and thus disproves that the leucocytes are destroyed. These results lead to the belief that the decrease in the number of the leucocytes in the beginning of leucocytosis is due to their obstruction and imprisonment, caused by the narrowing in the lumen of the capillaries, owing to the irritation of the endothelium by foreign toxic substances.

Medical Necrology.—An Austrian statistician finds that the average lease of life of a medical practitioner is sixty years. Deaths due to tuberculosis only amount among them to 7 per cent., thus showing how careful they are in taking precautions against infection. On the other hand, fully 40 per cent. of doctors die of heart disease and nervous collapse.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, MAY 21, 1904.

THE FUNCTION OF THE EOSINOPHILE.

EVER since Ehrlich's discovery and demonstration of these peculiar white blood cells containing large granules which stain so well with eosin it has been an insistent problem in the minds of pathologists and physiologists as to what the special function of these cells might be. It seems impossible not to conclude that they must have a definite and very specialized purpose seeing that their constitution is apparently so different from that of all the other white blood cells. In a paper read before the meeting of the Association of American Physicians, held in Washington last week (see Society Proceedings in this week's MEDICAL NEWS, page 997), Dr. E. L. Opie, of Baltimore, gave the results of his studies of the relation of cells with eosinophile granulations to bacterial infection which seem to show that these leucocytes play a very important rôle in the matter of vital resistance to bacterial invasion.

Within a few hours at most after virulent infection of an animal in the peritoneal cavity all the eosinophile cells in the peripheral circulation have practically disappeared. With milder and more chronic infections it may take longer for the eosinophiles to disappear, but eventually it becomes very difficult to demonstrate any of them in blood drawn from the surface of the body. On the other hand, if the infection is of a kind to which the animal does not eventually succumb, the eosinophiles begin to make their appearance once more and then increase until they have reached a number twice as great as they were originally. This increase of the eosinophiles is accompanied by a corresponding relief from the symptoms produced by the infection until the animal has completely conquered it. For instance, when guinea-pigs are injected with *Bacillus pyocyaneus* the eosinophiles will be found to have disappeared entirely from the peripheral circulation at the end of twenty-four hours. This form of infection is usually recovered from. With the decrease in the eosinophiles there is an increase of polynuclear leucocytes, but after the twenty-four hours have elapsed the eosinophiles begin to make their appearance once more and on the fifth day they have risen to double the normal number for the animal experimented on.

Under these circumstances the fate of the eosinophiles during their interval of disappearance becomes a very interesting problem, which, however, Dr. Opie seems to have solved completely. When the injections of infectious material are made into the peritoneal cavity the eosinophiles begin at once to accumulate in the blood-vessels of the omentum and the mesentery. Positive chemotaxis is so powerful that even an hour after the injection of virulent infectious material these granulated white cells can be seen adhering to the walls of the veins of the mesentery and can even be detected beginning to migrate through the vessel walls into the surrounding tissues. Here they do not act as phagocytes apparently, certainly not to any very marked degree, though a number of large mononucelar cells can be seen performing phagocytic action. As a matter of fact, alongside these macrophages of Metschnikoff, the eosinophile cells seem to be more or less inactive. Foreign observers reported having seen eosinophile cells when lying in contact with bacteria apparently direct their granular material in a more or less continuous stream toward that pole of the cell near which bacteria lie with the gradual disappearance of their granules. This curious biological phenomenon was supposed to represent some protective action on the part of the eosinophiles, but the observation has not been confirmed.

A very interesting set of observations seems to show that the eosinophiles may, as myelocytes, find their way from the bone marrow through the intervening circulation to the spleen and be re-

tained there for some time, in the meantime multiplying rather freely. This has undoubtedly led to the conclusion that eosinophiles frequently originate in the spleen.

While the eosinophile reaction seems to differ very markedly regarding the reaction of vegetable and animal parasites, for, as is well known, with *Trichina* there is an increase in the number of eosinophiles to be found in the peripheral circulation, Dr. Opie is of the opinion that this difference is more apparent than real and that the eventual increase of the eosinophiles in bacterial invasions which are not fatal shows that these cells, as in the case of infection with animal parasites, play some important rôle in the maintenance of vital resistance against parasites of all kinds.

INFLAMMATION OF THE OMENTUM.

That infection is the etiological factor of omental adhesions is probably admitted by all surgeons. In his important experimental work on the subject, Brink comes to the very just conclusion that this is absolutely essential, because he found that simple scarification of the peritoneum was insufficient to produce adhesions between it and the omentum, while if the parts were injected with *Staphylococcus pyogenes* such adhesions always occurred. As still another proof of the part played by infection in the production of omental adhesions, we would point out that when they spontaneously occur, that is to say, without traumatism, operative or otherwise, it is always after some infectious process has taken place in the abdominal cavity.

How does the infection spread? A study of the diseases of the female genital organs, such as metritis, ovaritis, salpingitis brings into prominence the close anatomical relationship of these organs. This relationship also extends to the pelvic peritoneum. A pelvic peritonitis, or rather a torpid attack of pelvic peritonitis, is invariably accompanied by an inflammation of the female genital organs, and although it has been upheld by Treves that the omentum never reaches as far as the pubis, the fact nevertheless remains that in many autopsies and laparotomies the lower border of the omentum is found not only reaching the pubis but it dips down into the pelvic excavation. The omentum, therefore, can readily come in contact with infected pelvic viscera.

This involvement of the omentum in pelvic inflammatory processes has been the subject of both clinical and pathological studies. In 1900 Braun pointed out that a tumefaction of the omentum frequently occurs after its partial resection in the radical operation for hernia and in certain gynecological affections. Inflammation of the omentum reveals its presence by severe abdominal pain, resistance on palpation accompanied by symptoms of intestinal occlusion. Its evolution is either toward resolution, abscess formation or chronicity.

Pathologically, inflammation of the omentum has been more especially observed during operations for appendicitis. The organ is red and presents a granular aspect, due to an excessive vascularization. Small extravasations or little hemorrhagic foci are observed and, not infrequently collections of rosy serum mixed with pus are found, especially among the adhesions. Microscopically one finds the lymphatics gorged with leucocytes.

Such is the acute form, but the process may evolute toward the chronic type and then the omentum retracts, thickens and finally forms a tumor. On examination, the omentum is found hyperemic and in many places a number of white, hard nodules, varying in size can be distinctly felt in its substance. These nodules are foci of subacute inflammation of the organ, which microscopically are found to contain broad bands of adult connective tissue fibers, representing vascular connective tissue of inflammation. Inflamed interstitial cells mixed with a few young connective tissue cells, form small masses situated between the adult connective tissue fibers. Occasionaly the fat lobules have disappeared in these foci and the few fat cells that still exist show evidence of irritation. Their nuclei are multiplying and some cells may contain as many as ten or twelve. The cell itself is diminished in size.

In other instances the fat lobules exist in quantities, so much so that they may form true lipomata.

The endothelial structures become hypertrophied while in places blood pigment is found indicating a former hemorrhage during the acute stage of epiploitis.

The omentum becomes retracted. This affects the stomach directly. Traction on the omentum does not produce gastrectasis, strictly speaking, but a gastroptosis results and secondarily a true dilatation of the viscus may ensue. Debet demonstrated experimentally that traction on the omentum was transmitted to the pylorus by means of the greater curvature and that under certain conditions that might produce a fold which diminished its caliber; but in the greater number of cases this is not the principal obstacle to empty-

ing the stomach, because when one draws the omentum down the movable portion of the duodenum comes down along with the stomach, while the second portion remains fixed and between the fixed and movable portions of the duodenum a decided curvature results which decreases the lumen and becomes an obstacle to the free emptying of the stomach.

Stasis of the stomach contents results; vomiting ensues accompanied by all the ordinary symptoms of fermentation and its consequences. A temporary dilatation occurs, which finally becomes permanent.

It would seem then of importance to search for lesions of the appendix or the female genital organs in cases presenting intractable digestive symptoms, for in still another instance can it be shown that interference with gastric motility is an efficient cause of great gastric distress. Surgical remedial measures offer hope in some of these conditions.

FREQUENCY OF LEAD POISONING.

THERE seems to be no doubt now in the minds of those best situated to have definite knowledge in the matter that lead poisoning is much more frequent in this country than is usually thought. Two years ago Prof. Osler announced as the result of the careful collation of the statistics of Johns Hopkins Hospital for a period of twelve years, with those of St. Bartholomew's Hospital, London, for the same time, that gout was comparatively much more frequent in this country than had been imagined. He added that American gout was usually earned and not inherited and that the two underlying pathological conditions on which it developed were changes in the system brought on by too free indulgence in malt liquors and the presence of lead in the tissues. According to the statistics of Johns Hopkins Hospital, for every four patients admitted to St. Bartholomew's Hospital suffering from gout three patients suffering from the same disease are admitted to Johns Hopkins. Possibly at least one-third of our American cases of gout are due to chronic lead poisoning.

It is too often the custom to think that plumbism gives very characteristic symptoms that can scarcely fail of recognition. Lead colic, plumbic constipation, wrist-drop and the blue line on the gum, while usually present, are by no means necessarily in evidence, or their occurrence may be so masked by other circumstances as not to be definitely characteristic. Very few painters entirely escape the effects of lead in the system. This is especially true now that the painting of ceilings and of the walls of high buildings compels painters to work in such positions as to have the lead on their brushes above their heads for a good part of the time while they are at work. Recently Sir William Gowers again reminded the profession that it is almost impossible for a painter to escape the absorption of lead in toxic amount under such circumstances.

The tradition in the painting trade, however, is that only about one in three or four suffer from lead poisoning and these are supposed to be unfortunate individuals in whom an idiosyncrasy causes even small amounts of lead to produce serious effects. Such individuals suffer from the very beginning of their occupation as painters. It is well recognized that there is a marked idiosyncrasy existing in certain people, which makes them liable to suffer from even minute amounts of lead. It has happened repeatedly in country houses that while a whole family has taken the water from a newly constructed reservoir flowing through new lead pipes, only one member of the family has suffered from the small amount of lead that was dissolved in the water owing to the presence of slight amounts of carbonic acid or some of the carbonates in it. No human system, however, will stand contact with lead for a protracted period without suffering severely, and it is the latent cases which prove eventually more disastrous than the frankly acute toxemias that develop early in the association with lead. The lead kidney may develop very insidiously. Serious lesions of the nervous system may give only slight symptoms for a considerable period. A little awkwardness in the use of the forearm and hand may be noticed for many months before some injury, such as a sprain of the wrist, brings on an attack of characteristic wrist-drop showing how saturated with lead the nervous tissues have become.

In his recent series of clinical lectures Sir William Gowers calls attention to the ease with which cases of lead poisoning may be overlooked, unless the physician's attention is especially called to this question. One of the cases which he discusses at some length had evidently come to him from America where the diagnosis of hopeless and progressive muscular atrophy had been made, though his discovery of a lead line on the gums caused him to give a favorable prognosis at once. In this case at first sight the gums seemed normal. But on more careful inspection and espe-

cially on examining the gums of the upper jaw with a lens, several spots were found at which there was a slight separation from the teeth and at these points Sir William found two or three indubitable fragments of the characteristic lead line.

In the course of this lecture Sir William dwells on the characteristics of the lead line on the gums, as he has seen it. He says it is typical in proportion as it approaches Euclid's definition of length without breadth, always provided it is black. Contrary to the usual text-book declarations in the matter, according to which it is said to be blue, Gowers has never seen any color in it. It is never present unless the gums are slightly separated from the teeth. It may exist only at two or three isolated spots or on the tips of the projections of gum between the teeth. It can then only be found by a most careful and thorough search on the upper jaw as well as the lower. He insists that the smallest fragment, if distinct, is as significant as the most extensive deposit.

Gowers emphasizes particularly the number of forms of nervous disturbance that may be due to lead poisoning. The brain itself may suffer and saturnine encephalopathy is not very infrequent and is usually attended by optic neuritis. The common peripheral neuritis of which wrist-drop is the characteristic manifestation is only one of its effects. A slow chronic atrophy of the muscles of the forearm and hand, affecting first the interossei and developing exactly like spinal atrophy, is far more enduring than the wrist-drop and may even become permanent. Optic nerve atrophy alone, without brain symptoms, may be due to lead, and it may cause slight forms of sclerosis of the cord. Tremor may occur and chronic convulsions that simulate epilepsy. He has also found hysteria, especially in predisposed subjects. While headache is a frequent effect, neuralgia of great severity may be the most prominent symptom of the disease. On the other hand, symptoms of general nervous weakness without any definite localization may be due to lead poisoning that gives no other manifestation of the toxic process at work in the system. This affection only too often masquerades as neurasthenia and is but another proof of the abuse of that unfortunate word.

Philadelphia Hospital.—Miss Mary McDonnell has been appointed assistant chief nurse in the Philadelphia Hospital. She comes from the Massachusetts General Hospital and takes the place made vacant by the resignation of Miss Lippincott.

ECHOES AND NEWS.

NEW YORK.

Alumni Association College of Physicians and Surgeons.—The annual meeting of the Association will be held at Sherry's, Wednesday, May 25, 1904, at 8.30 P.M. Members are requested to notify the Secretary, Dr. H. E. Hale, 150 West Fifty-ninth Street, before Tuesday, May 24, if they expect to be present.

Tuberculosis Clinic.—Dr. Thomas Darlington, President of the Board of Health, decided to open a night class at the Tuberculosis Clinic of the Department of Health at 967 Sixth Avenue, the hours being from 8 to 9 P.M. on Monday, Wednesday and Friday. This evening class began last Monday, May 16, 1904. Two doctors and two nurses are in attendance and all medicines are furnished free of charge. Since the opening of the Clinic on March 1, 1904, from 250 to 300 patients a week have been in attendance from 9 A.M. to 4 P.M. This new clinic is for those patients who are unable to attend during the day. Special cards for the reference of patients to the clinic for diagnosis or treatment will be furnished on request. Physicians and others interested are cordially invited to visit the Dispensary.

Commencement at Woman's Medical College.—Five young women were graduated last week at the forty-first annual commencement exercises of the New York Medical College and Hospital for Women. The young women who subscribed to the Hippocratic oath, administered by Professor M. Belle Brown, the dean of the faculty, were May Darrach, Ethelyn Augusta Frances Fuller, G. Holm, Isabella Thompson Smart and Mary Sutton Macy. The prize for the highest average for four years' work was awarded to Miss Macy. Mrs. Jean Williams won the junior prize in medical jurisprudence, Miss Edwina Frick the sophomore prize for the best work in anatomy and Miss Eleanor Van Buskirk the freshman prize for highest standing.

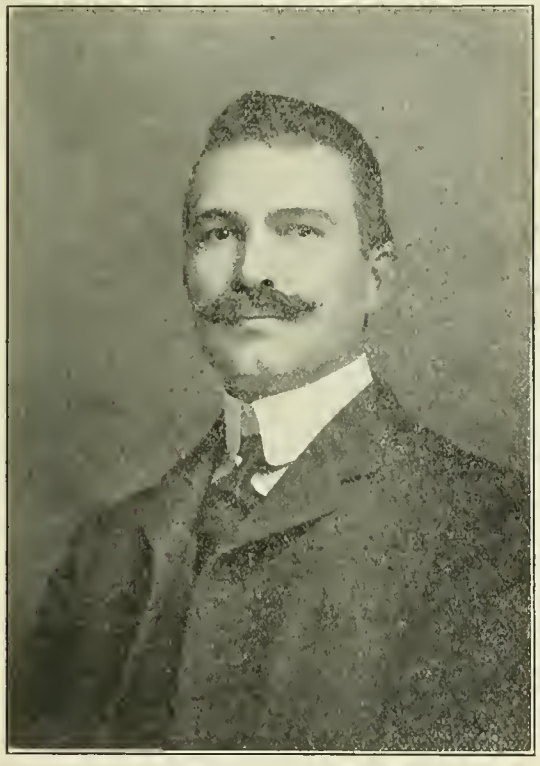
Examination for Superintendent, Rome State Custodial Asylum.—An open competitive examination will be held at Albany, Buffalo, New York and Syracuse, June 3, 1904, for the position of superintendent of the Rome State Custodial Asylum. The authorized maximum salary is $4,000 with maintenance for the superintendent and family. The statute requires that the superintendent "shall be a resident of this State, a well-educated physician and graduate of a legally incorporated medical college," and must "have had a suitable experience and training of not less than three years in the care and treatment of the mentally defective classes, epileptic or insane." Subjects of examination and relative weights: Laws relating to the institution and the commitment, care and treatment of the dependent and defective classes, 1; institutional care, training and treatment of the custodial class of feeble-minded persons and idiots, 3; institutional supervision, administration and discipline, 2; education, experience and personal qualifications, 4. Persons desiring to enter the examination must execute applications on forms supplied by the Commission and file them in its office before noon of June 1. For application blank, address Chief Examiner, State Civil Service Commission, Albany, N. Y.

Director of Pathological Laboratories, Bellevue Hospital.—The Civil Service Commission will hold a competitive examination June 7, 1904, for Director of Pathological Laboratories, Department of Bellevue and Allied Hospitals. Applications will be re-

ceived from residents of the State of New York until May 28, at 61 Elm Street. The salary is $5,000 a year and the successful candidate will be required to devote all his time to the work, abstaining from private practice or connection with a medical college.

Addition to Loomis Sanatorium.—Through the efforts of the Children's Guild of the Loomis' Sanatorium a Children's Cottage has just been opened in connection with the Annex where it is possible to care for twelve children under fifteen years of age. There are in this cottage two supported beds and the other ten patients will be received at the regular Annex rate of $5 per week. As a competent nurse is in charge, even young infants can be admitted. Candidates for admission to this division of the Sanatorium need not be cases of pulmonary tuberculosis necessarily but glandular and bone cases and such surgical cases as have been operated upon and require such climatic advantages and environment as can be accorded them during convalescence, will be received. A separate dietary adapted to the requirements of these young patients will form a feature at the Children's Cottage. Applications for admission may be made direct to the physician-in-chief or to any member of the medical staff of the Sanatorium.

New Head for Bellevue.—At a meeting of the Board of Trustees of Bellevue and Allied Hospitals, held last Friday, a resolution was adopted appointing Dr. William P. Spratling, Superintendent of the Craig Colony for Epileptics, at Sonyea, N. Y., to the Superintendency of Bellevue Hospital, vice Dr. William Mabon, resigned. Dr. Spratling will begin his new duties on June 1. Dr. Spratling's career has been one of exceptional promise. He was born in Chambers County, Alabama, October, 1863, and was graduated in medicine from the College of Physicians and Surgeons of Baltimore in 1886. Following graduation he was Demonstrator in Chemistry and Assistant Resident Physician at the Maryland Maternity Hospital. For five years he was on the staff of the New Jersey State Hospital for the Insane at Morris Plains, and in 1895, after a competitive examination, was appointed Superintendent to the Craig Colony for Epilepsy. Following his appointment Dr. Spratling went for a second time to Europe, continuing his study of institutions for the insane, and on his second visit he lived for some time in the German Colony for Epileptics at Bielefeld. He has been instrumental in converting a wilderness at Craig Colony into a well-laid out village of sixty-six buildings, and an equipment capable of taking care of fully 10,000 people, and has brought into practical realization the hopes and plans of those interested in epilepsy at the Colony, making it a model for all time and for all countries. With such a leader New York City can hope for great things in the future.



Dr. William P. Spratling.

Defense of Insane Hospitals.—Dr. William Hirsch recently sent to the *Times* a long letter explaining away apparent abuses of the insane in State hospitals and exonerating the attendants. He says in part: "From time to time there are reports published in some of the daily papers of alleged 'cruelties' against patients committed to the Manhattan State Hospital. There are constantly about 4,000 patients under treatment in the hospitals of Ward's Island, and if we assume that each patient has an average of five relatives who are concerned in his welfare, these articles are likely to startle about 20,000 people and to give them infinite worry by making them believe that their relative is at the mercy of heartless brutes, and is subjected to the most atrocious cruelties. It is for this reason that I think somebody who is thoroughly familiar with these hospitals should be heard on this subject.

"A great many insane persons suffer from a symptom called delusions of persecution. Patients of this kind complain constantly about their assumptive enemies, who have formed a conspiracy against them and who torture them in all possible ways. As soon as these patients enter the hospital they imagine they are being poisoned and tortured by the officers of the institution. If in addition to their delusions they suffer from hallucinations, they actually see and hear their enemies who maltreat and torture them. Their stories are sometimes so plausible that a layman will invariably believe them, not being able to recognize the fact that a person may talk quite coherently and still be insane.

"It is possible, of course, that in the attempt to restrain, feed, or clean a patient forcibly a nurse may act awkwardly and perhaps inflict an injury which a more skilful nurse would have avoided; but is that a case for the District Attorney? No more than a case of septic infection in a surgical ward. I want to assure people that their friends in the hospital are treated according to the most modern scientific principles: that everything that possibly can be done is being done for them, and that there prevails only one spirit in the Manhattan State Hospital, and that is the spirit of humanity."

PHILADELPHIA.

Methodist Hospital.—A bequest of $20,200 by John N. Doak provides for four free beds in the Methodist hospital.

Pasteur Institute Desired.—The officials of the Bureau of Health are strongly in favor of establishing here an institute for the treatment of rabies. The recent preventive treatment of two persons

through the kindness of the New York Health Department has led to the suggestion that a laboratory be founded in this city. Several deaths from hydrophobia have recently occurred.

Streets to Be Flushed.—To get rid of the great quantities of dust on the streets at the present time the street-cleaning contractors are hereafter to flush the streets daily from the fire plugs. In addition, Market and Chestnut streets are to be sprinkled every two hours, from 8 A.M. to 6 P.M. Chief Sutcliff refuses to entertain the idea that the dust spreads contagion and looks upon the new measures as only conducing to the comfort of the public.

Philadelphia Hospital Examinations.—The examination of candidates for resident physicians of the Philadelphia hospital was held May 10. Ninety-five applicants, among whom were three women, took the examination. The examining board consisted of Drs. John H. Gibbon, W. T. Longcope, and W. E. Hughes. Nineteen positions are to be filled.

New York Certificates to Be Credited.—As the result of a recent conference, it is announced that certificates of preliminary examination in New York will be given full credit by the Pennsylvania State Board of Medical Examiners. Some months ago this privilege was refused which caused great dissatisfaction among many medical students.

CHICAGO.

Donation of $75,000 to the Maurice Porter Hospital.—The Maurice Porter Hospital will be known in the future as the Children's Memorial Hospital. Mrs. Porter has given $75,000 toward a new building in memory of her son. This institution will be the nucleus of a new hospital where adequate provision for the care of the poor children of Chicago will be made.

Money for Augustana Hospital.—At the Illinois Conference, Augustana Lutheran Synod, the Board of Directors of Augustana Hospital, Chicago, was authorized to borrow $100,000, with which to erect an addition to the Hospital. Dr. M. Wahlstrom was elected Superintendent of the Hospital, and Dr. C. G. Folsom, of Galesburg, and Dr. Theodore Freeman, Chicago, were elected members of the Hospital Board.

Rents Old Training School.—The Board of Trustees of the Dearborn Medical College has leased the old Chicago Manual Training School Building, Twelfth Street and Michigan Avenue, together with the Pharmaceutical Department of the University of Illinois. Because of the removal of the school to its new quarters, the series of lectures to the police on first aid to the injured will be abandoned temporarily.

Music for the Insane.—Dr. V. H. Podstata, Superintendent of the Dunning Institutions, in a recent address stated that the salutary effects of music on the disordered mind are many and profound. "The first effect of pleasing, harmonious sounds is a relaxation of special nervous tension. The harmonious sound wave reduces the horrible inhibition and the mental agony of the melancholy patient. It liberates the pent up energy and diverts the association of ideas. In the maniac the constant flight of ideas and motor restlessness is moderated and often checked. In the purely deluded the attention is diverted so that at least temporary stay is achieved in the abnormal mental aberration constantly inclosing the poor mind in a deep network of delusions. The demented patient is stimulated and aroused to activity. In all cases the harmonious impressions cause a relaxation of circulation of blood. The congestion is relieved, also the anemia, and, as a result, not only the brain, but all the organs of the body are enabled to return to the normal activity. The stomach can now secrete sufficient quality and quantity of digestive ferments, and the elimination of poisonous waste products increases. As a further result, reconstruction may take place and the patient be given better chance for improvement. What, then, is the philosophy of the effect of music upon the brain? Surely no one can expect that the structural weakness of the brain, due to impediments in development from hereditary causes, will be corrected by a melodious harmony of sound. Neither can the sweetest music remove from the blood the alcoholic or other poisons causing a steady deterioration of all tissue, particularly the highly organized and sensitive associative nervous network in the brain.

The Evolution of the Modern Operation for Entropium of the Upper Lid.—Dr. F. C. Hotz read a paper on this subject before the Chicago Medical Society. In the normal lid the free margin stands perpendicularly on the eyeball and also forms with the eye lashes approximately a right angle, keeping the latter at the same distance from the globe in all the movements and positions of the lid. In entropium the lid margin inclines towards the eye and carries the cilia down with it so that they touch the globe and cause more or less irritation by friction. For the relief of this irritation the cilia must be turned away from the eye; three different schemes were employed: skin traction, changing the curvature of the cartilage, and the making of a new lid border. Along each of these lines the operations were gradually perfected and out of the combination of them evolved the modern entropium operation. The traction scheme is the oldest, it attempts to turn the inverted lid border straight by traction exerted upon it through the skin. A study of the operations based on this scheme shows the following course of evolution: (1) Traction through ligatures, which produced a hideous deformity of the lids. (2) Traction through shortening the skin, which handicapped the lid in its movements so that it could not be closed. (3) Traction through skin shortening combined with sliding the cilia upward on the tarsus, which had the same mutilating effect, and finally (4) traction by drawing the lid skin up and fastening it by sutures to the upper border of the tarsus. This method secures a constant and uniform tension without mutilating the lid. But traction alone is not effective enough in the higher degrees of entropium, especially if complicated by irregular growth of the cilia. To facilitate in such cases the upturning of the lid border the scheme of grooving the cartilage was introduced. One way was to make a transverse incision through conjunctiva and tarsus above the margin. This proved a complete failure because this transverse groove on the conjunctival side of the tarsus filled up with cicatricial tissue the contraction of which necessarily drew the lid border down again. The other way was rational and successful. It is Streatfield's operation of removing a transverse wedge-shaped piece from the cartilage, the base of the wedge being on the cutaneous side of the lid and the apex near the conjunctival surface. Therefore if the edges of this groove are brought together the lid border with the cilia is turned up. The scheme of turning up the cilia alone and supporting them by a new lid margin was first suggested by Spencer Watson in 1874. He slid the cilia up on the tarsus, like Arlt, but instead of holding them in their

new position by skin traction he supported them by a skin flap transplanted below. This method then passed through a number of modifications and finally developed into the simple but effective operation of splitting the lid border deeply, turning the cilia bearing edge up and filling the groove under the cilia in the margin with a slender Thiersch graft. If to this rebuilding of the margin is added the fixation of the lid skin to the upper border of the tarsus the operation yields perfect results. Thus evolution has led to two excellent methods; the combination of grooving the cartilage with skin traction from the upper border of the tarsus, and the combination of rebuilding the lid margin with skin traction from the upper border of the tarsus.

Radical Mastoid Operation for Chronic Purulent Otorrhea.—In a paper on this subject, Dr. Frank Allport pointed out the reasons for and objections to the radical mastoid operation for the permanent relief of chronic purulent otorrhea. The writer believed that the asking of a single question should place the necessity for the radical mastoid operation for the relief of chronic purulent otorrhea in its proper light. Why should ordinary rules of surgical expediency, which point to the removal of necrotic and dangerous tissue in other portions of the body, be more or less ignored in cases of intractable chronic purulent otorrhea? This question was emphasized by the fact that in almost all such cases the morbid changes were not confined to the middle ear space, but were continued back through the aditus ad antrum to the antrum, and usually into the mastoid cells. The dangers of the radical mastoid operation were such that, while they should not deter a competent and progressive surgeon from undertaking the work after the conviction for its necessity had been reached, the operation should not be performed without much study, experience and observation, and not until its urgency was conscientiously manifested. The chief objection to the radical mastoid operation was the production of facial paralysis (an accident which should seldom, if ever, occur after the operation for acute mastoid abscess), and this was a menace of no mean caliber, and one from which the average operator might well shrink. The facial nerve might be injured in any portion of its course during the operation, from its entrance into the middle ear at the upper, middle portion of the tympanic wall to its exit from the skull at the stylomastoid foramen. Another danger to be avoided during the radical mastoid operation is the infliction of an injury to the horizontal semicircular canal. The wounding of the sigmoid portion of the lateral sinus was undoubtedly one of the dangers of the radical mastoid operation, although the author believed that this danger had been very much overestimated both as to its probability and also as to the damage accomplished by such an accident. Another danger in the radical mastoid operation was the possibility of exposing the dural covering of the temporosphenoidal lobe or the cerebellar lobe of the brain, and this danger had been much overestimated. But little anxiety need be entertained even if such an accident should occur. While meningitis and other intracranial complications and accidents to the facial nerve, horizontal semicircular canal, sigmoid sinus, etc., may result from the performance of the radical mastoid operation, the only occurrence that seemed to the writer to sustain much weight was the embarrassing and unfortunate occurrence of facial paralysis. Another objection to the operation was the fact that the ultimate result was not always successful as to the cessation of the discharge. A fourth objection, which was frequently raised, was the possible bad effect upon hearing. Purulent tympanic infections were responsible for about one-half of the brain abscesses of the world, and that in the United States alone four thousand otitic brain abscesses occurred annually, which proportion was trebled in Germany; that chronic purulent otorrhea was responsible for most of these, and that death occurred in about one in every thousand cases of ear disease of all kinds that came under treatment. Hundreds of cases of chronic purulent otorrhea presented themselves to physicians to be cured. Shall physicians be satisfied with eternally, month after month, and year after year, cleansing, drying, powdering, scraping these middle ears, when they must know that the real seat of the disease could never be even touched except by the radical operation?

GENERAL.

Ruling in Favor of Oxalic Acid.—Attorney-General Cunneen has decided that while grocers may not sell paregoric and witch hazel under the pharmacy law, they may sell oxalic acid. In an opinion addressed to George W. Ryan, president of the Buffalo Retail Grocers' Association, the Attorney-General says: "Oxalic acid is largely used in calico printing, dyeing, and the bleaching of flax and straw. I do not know of any use to which paregoric and witch hazel are put to other than in the field of medicine. I am of the opinion that paregoric and witch hazel may not lawfully be sold by grocers and that oxalic acid, although a dangerous poison, may lawfully be sold by grocers for use in the arts, but not for any other purpose. Oxalic acid, when at all sold, must, of course, bear the poison label as required by Section 198 of the statute.

We may henceforth reasonably expect a decline in the use of carbolic acid as a self-destroyer in favor of its powerful ally so easily procurable under the above conditions.

Physical Training and Heredity.—A very interesting if not entirely satisfactory set of conclusions have been arrived at through the excogitations of M. Tissié, physical director in the Bordeaux Academy in Paris. M. Tissié believes that the maintenance of a fair degree of health depends upon the proper distribution of bodily energy between body and brain, and that overwork of either results in mental or physical fatigue. In his estimation no training that suppresses appetite, increases thirst, or disturbs sleep can be beneficial in the slightest degree. Excessive exercise means a foundation for a "double personality" and leads to "hysteria." On the psychological side general bodily movements of extension mean pleasure; while those of flexion tend toward grief. Furthermore it is possible to transmit the good or bad results of physical training to offspring and then to directly influence the well-being of a future race. On this point very special stress is laid. An attempt is made to classify various organs in the body according to their importance; viz., (1) brain, (2) lungs, (3) heart, (4) stomach, (5) splanchnic organs and glands, (6) muscles.

It is unfortunate that the gentleman in question has left so little proof either direct or indirect in support of his assertions, and it is always dangerous to theorize when there is a possibility that some one with a little more scientific acumen may obtain facts which shall disprove one's most carefully treasured bubbles. There seems to have been plausibility enough in the present instance, however, to merit the attention of reputable scientific journals, chief of which is the *Revue Scientifique*. In criticising M. Tissié's statements, this journal concurs in the idea that there is probably a potential general nerve force which can become physical or psychical according to the demands of the individual at any particular moment. Whether this force shall be

liberated as muscular energy, for example, or as its psychical equivalent, depends upon the constitution of the individual and upon his requirements. For instance, if the "valve of cerebration" is hard to open we have the hard-handed laborer or the athlete; if this so-called valve be easy to open we have the esthete.

This view is not likely to become popular in America, especially among our college athletes who object most decidedly to disparaging remarks concerning their mental capacity and who are quite anxious to prove the existence of an opposite state of affairs. Their view is reasonable enough, too, when one considers how excessively fatiguing a hard game of football is, and how very few heroes of the gridiron develop anything like the double personality or hysteria described by M. Tissié. As for the transmission of physical characteristics through heredity the fact seems pretty well established already and there is little more to be done about it save the collocation of well-marked and distinctively interesting cases as they may arise.

As illustrating the danger from mental overwork and consequent nervous breakdown, the *Revue* thinks that "the nervous are poisoned under the influence of overwork resulting in cerebral lameness," analogous to physical lameness from a like condition in the muscles. This may be a likely explanation, it certainly has the quality of being novel; but so far as the reporter's own experience goes most cerebral lameness seems to be of the congenital type and quite incurable by any manner of elaborate "exercise," fatiguing or otherwise.

The *Revue* thinks that the medical profession should take a more vital interest in these matters because its "ideas on these subjects are essentially rudimentary, since there are no courses of physical training in medical schools." It seems likely that if all the subjects one ought really to know come to be taught in medical schools, human life will have to be lengthened considerably beyond the Biblical three score and ten mark. One ought to be glad that he was graduated before he became fully aware of his reprehensible unfitness.

OBITUARY.

Dr. Clinton Cushing, one of the oldest and best-known physicians of Washington, D. C., died suddenly at his home on May 10. Dr. Cushing retired from practice some years ago.

Dr. William Waterworth, for twenty-two years a resident of Brooklyn, N. Y., where he was a practising physician, died May 11. He was born in Salem, Ohio, in 1851, was graduated from Adelbert College, and in 1878 from the Bellevue Medical College. He was a member of the Union League Club of Brooklyn, of the Royal Arcanum, and of several medical societies.

Dr. William H. McGee, a leading physician of Warren County, N. J., died May 11, aged fifty-six years. He was a member of the Warren County Medical Society and resident physician of the Pennsylvania Railroad Company.

CORRESPONDENCE.

CARCINOMA OF THE STOMACH.

To the Editor of the Medical News.

Dear Sir: I desire to draw attention to a clinical sign which has proven the means of putting me on the right track in cases which further examinations have proven to be gastric carcinomata. I refer to the stomach transparency which can readily be seen with the fluoroscope in many of these cases without previous distention of that organ with gas. In a healthy stomach the walls contract on the contents, but in cases of carcinoma they very early seem to lose this physiological power of responding to the presence of food and the fundal area remains continuously dilated and distended, even though there be no displacement downward of the lower gastric border and even though a glass or two of water be given to these patients to drink. The same fact can be to some extent brought out by percussion, but not so well, as the pulmonary emphysema, nearly always present in these cases, makes it difficult.

C. M. Cooper, M.B., M.R.C.S.

San Francisco, Cal., April 26.

POISONING BY EGG.

To the Editor of the Medical News:

Dear Sir: Apropos of Dr. Clemens' interesting instance of Poisoning from the White of Egg published in the Medical News of April 16, 1904, I beg to report a somewhat similar idiosyncrasy in a child, now three and a half years old, who has been under my care since birth; with the difference, however, that in my patient it appeared to be the yolk, and not the white, of egg which caused the untoward symptoms. The idiosyncrasy was first noticed when, at the age of twelve months, the raw yolk of egg was added to the infant's bottle of milk; this was followed in about two hours with great pallor and severe vomiting and prostration, twenty-four hours elapsing before the child had regained its usual health. A few weeks later a similar train of symptoms followed the admixture of a whole raw egg with the food. The raw white of egg alone was then added to the bottle, but was not followed by any disturbance. This peculiarity continued throughout the whole of the second and third year, the administration of whole egg or egg yolk, whether raw or cooked, always producing the symptoms described above. Lately, since the child has attained its third year, it is being educated to eat egg yolk, by giving it minute quantities of food containing the yolk, such as custards and farinaceous puddings, and so far no disturbance has followed.

The symptoms in my patient cannot be explained by gastric irritation alone, induced, for instance, by the large quantity of fat present in the yolk of egg; the symptoms were on each occasion of distinctly toxic character, the prostration being marked and prolonged, while some of the attacks were attended with fever. Nor could they have been due to decomposition changes; they followed whether State, city eggs or fresh country ones were eaten.

Idiosyncrasy as regards eggs is not uncommon. People constantly assert that eggs make them bilious. Sometimes this is imaginary, but in many cases the inability actually exists. Jonathan Hutchinson in his work, "The Pedigree of Disease (London, 1884), relates several cases of this nature, in some of which the symptoms were so violent as to excite suspicion that poison had been given. In the *British Medicol Journal* for March 11, 1899, there is the report of a case in which the very smallest quantity of egg caused the most violent symptoms, resembling those of an irritant poison; in this patient a small portion of white of egg placed on the skin was followed by an abundant urticarial eruption. Robert Hutchinson (Food and Diebetics, London, 1901), in speaking of idiosyncrasy in respect to eggs, says that the digestive juices of some persons apparently act in such a way as to produce poison when eggs are introduced into the stomach. In many cases it has seemed to the writer that the trouble lay in the yolk, possibly because of its large fat content. On the other hand, especially in the cooked egg, the white is undoubtedly the offending element; indeed, this would seem to be the case in the majority of instances—more, however, when

given in combination with the yolk than when eaten alone. Robert Hutchinson points out that the sulphur of the egg is contained almost entirely in the white, and that when eggs rot, and, in some cases during digestion, alkaline sulphides are developed, and these being acted upon by phosphoric acid produced from the yolk, sulphureted hydrogen is liberated, to which the symptoms may in some cases be due. However this may be, it is significant that eggs and fish, the two dietary articles with which individual susceptibility is most frequently associated, are the very ones most susceptible to changes from overkeeping.

Some of the instances of egg-poisoning are undoubtedly due to the changes in the eggs themselves; but others can only be explained by the term idiosyncrasy—a word, which according to J. Hutchinson, is intended to denote one ignorance of causes, though in no degree to express disbelief in their existence. I am, sir,

Very respectfully yours,

Philadelphia, April 27. D. J. Milton Miller, M.D.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Nineteenth Annual Meeting, held at Washington, D. C., May 10 and 11, 1904.

(Continued from Page 955.)

Second Day—May 11th (*continued*).

Eosinophiles and Bacterial Infection.—Dr. F. L. Opie, of Johns Hopkins, Baltimore, described some recent observations on eosinsphile cells, made with the purpose of determining the relation of these cells to bacterial infection and bodily resistance to bacterial invasion. Various observations in this line have been made but they are not all in accord. Observers saw the granulations streaming toward the part of the eosinophile cell that happened to be in contact with a bacterium and then disappear as if in their dissolution some protective purpose was involved; other observers did not confirm these observations, however. Ehrlich found in his investigations of cells that shortly after infection the polynuclear leucocytes were increased and that, apparently at least, the eosinophiles were reduced in number. This observation has been amply confirmed and it is now generally conceded that in fevers the eosinophiles are decreased in number.

Bacterial versus Animal Parasitic Infections.—While in bacterial infections this reduction of the eosinophiles always occurs with animal parasites, as the *Trichina* and most of the intestinal parasites there is an increase of eosinophiles. This is true also in diseases such as smallpox and scarlet fever, in which the presence of an animal parasite as the causative factor is suspected and in malaria, where this type of parasite is known to be the cause. This difference in all reaction promises to be of diagnostic significance for obscure forms of disease due to animal parasites.

Study of Eosinophiles.—Guinea-pigs have normally 5 to 6 per cent. of eosinophiles, so that the study of these formed elements in them is comparatively easy. Chronic infections, as tuberculosis were found to bring a decrease in the number of eosinophiles. This was true also for such infections as would ordinarily cause the death of the animals in about a week. No eosinophiles were to be seen in the circulation when the fatal termination was approaching in these diseases. They had disappeared also from the tissues. In acute infections the disappearance was much more rapid. In severe infections a few hours sufficed to bring about the disappearance of these cells. The *Bacillus pyocyaneus* caused their disappearance in about twenty-four hours. As a rule, guinea-pigs recover from this type of infection and the diminution of eosinophiles is found to correspond with an increase in the polynuclear cells. On the second and third day the eosinophiles reappeared then gradually increased beyond their original number.

Fate of the Eosinophiles.—The eosinophile cells have disappeared from the peripheral circulation but they can be found accumulated near the point of infection. When the infection is in the peritoneal cavity where the pathological picture can be studied so well, the eosinophiles are found in immense numbers in the veins of the omentum and mesentery and also escaping from these into the surrounding tissues. This process of adhesion to the walls of the veins and migration can be seen within an hour after an acute infection. The eosinophiles do not seem to act as phagocytes, though certain other cells, *e.g.*, the large mononuclear cells which accompany the eosinophiles do. These latter are the macrophages of Metschnikoff.

Life History of Eosinophiles.—The life history of some of the large eosinophiles is extremely interesting. They seem to originate in the bone-marrow, and are carried thence in the circulation to the spleen where for a time they are harbored in the reticular spaces. Here they seem to find favorable circumstances for their multiplication and the occurrence of this process might easily give rise to the thought that they originated here. It is from here that they eventually find their way into the system for the exercise of their normal physiological functions.

Conclusions as to Eosinophile Life.—Dr. Opie considers that it must be concluded that eosinophiles respond to chemotaxis and find their way immediately to the neighborhood of an infected focus. Here they but rarely act as phagocytes, but they play some other rôle in the mechanism of protection, or at least attempted reaction against bacterial invasion.

In reply to a question, Dr. Opie, in closing the discussion, said that at first bacteria cause a decrease but subsequently an increase of eosinophiles while animal parasites cause an increase from the very beginning of their habitation within the organism. This phenomenon is strikingly diverse, yet there is in the end a similarity that points probably to more or less identity of action and reaction.

Chloroma with Leucemia.—Dr. George Dock, of Ann Arbor, Mich., reported a new case of the rare disease chloroma, that is, the occurrence of greenish tumors at the same time with a leucemic condition of the blood and presented a study of all the cases of the disease that have been reported since 1893. Formerly this affection was considered to be some sort of pernicious anemia. Later it was thought to be a form of leucemia complicated by a tendency to the formation of malignant tumors. The tumors were generally considered to be sarcomatous. Usually a decided weakness is one of the first symptoms of the disease and this is followed by the development of exophthalmos and the occurrence of tumors in the temporal regions with symptoms of their presence within the skull and also along certain of the bones. Dr. Dock's case began at the age of forty-five years, without any known cause, and weakness was such a prominent feature very early in the affection that the patient stayed in bed almost from the very beginning.

Symptoms.—None of the external lymph glands were enlarged, though there was a very marked leucemia. While preparations were being made for more detailed study of the blood itself and of the secretions, especially the urine, the patient unexpectedly succumbed to the disease. At the autopsy a number of

green tumors were found lying along the front of the vertebræ, just behind the sternum at the origins of the muscles and in most of the internal organs, especially the liver, kidneys and lungs. This very general invasion shows that the disease must have been at work some time before the first symptoms declared themselves, or at least before the patient would submit to thinking himself ill. The consequence was the unexpected death.

Blood Peculiarities.—The blood contained very few large nucleated red cells and in general, the red cells were affected only as in severe secondary anemia. Eighty per cent. of the white cells, however, were different from any ordinary blood cells and resembled bone marrow cells. A much greater proportion than normal of the white cells were eosinophiles. Some basophiles were seen but only just before death occurred. Unfortunately no autopsy of the head was allowed, so that it was not sure whether any tumors were present there, though there were no clinical symptoms pointing to this. The long bones also could not be examined and it is in these particularly that many interesting features of chloroma are discovered.

Comparative Frequency of Chloroma.—So far in the literature there are over a score of cases of chloroma, but observations on this type of disease have multiplied rapidly since special attention was called to it in very recent years. Within the last year at least six cases of chloroma have been seen. It seems not unlikely that in the next few years it will be found that chloroma is by no means a rare disease and at the present moment it would seem that clinicians generally should look for it. In all the cases in which complete autopsies have so far been made, greenish tumors have been found at the base of the skull. These are particularly likely to be present in the temporal fossæ. Occasionally the disease is recognized during life, because of tumors growing in the orbit and causing exophthalmos, these tumors also growing into the eyelids and showing distinctly green beneath the conjunctiva.

Tumor Coloration.—Dr. Byron Bramwell said that he reported a case in which the tumors when first seen were of a distinct, somewhat dark slate color. The shade being what would be called cyanotic. Later a distinct greenness developed not unlike that which is seen when, as a bruise is getting well the original black and blue change to green. Many shades of green, however, are seen, from a light sage green, such as occurred in Dr. Dock's last patient to a darker, yet bright green. Often these tumors are found before the condition of the blood is recognized. In one case the removal of the jaw for what was thought to be a sarcoma showed the presence of a greenish tumor, which had also invaded the skull and had many of the symptoms of malignancy. No chemical or biological explanation of the color has so far been found. Recklinghausen's suggestion that it is of parenchymatous origin somewhat as green pus (not that due to any of the actively coloring bacilli) is generally considered to be the only available explanation as yet. Certain of the clots found in the heart in leucemia have a greenish tinge but the heart clots are usually less green than are these tumors.

Blood Picture.—The blood picture must remain the most characteristic feature of the disease. It is that of a lymphatic leucemia but with some specific differences. Usually there is an enormous number of eosinophiles. There is nearly always an increase in the number of neutrophiles. Large lymphocytes are found in large numbers but some lymphocytes are also seen. In general it may be considered a more malignant type of leucemia. When there is an increase in the number of eosinophiles in leucemia, then the patient must be carefully looked over for the presence of any tumor formations and any hint of a greenish appearance.

Dr. Osler said, in discussing Dr. Dock's paper, that it may be well to try and get at the clinical picture of the disease, in order that clinicians may be ready to have suspicions aroused with regard to it, for it is evident that the affection is much more frequent than the number of cases so far reported might lead us to think. The leucemic condition would naturally last for a considerable period. When it is accompanied by great weakness, this should always be a suspicious sign.

Similarity to Scorbutic Leucemia.—Dr. Dock, in closing the discussion, said that not all the cases of chloroma reported have run so severe a course as his own. As a rule, indeed, they have had a very close similarity to leucemia, due to digestive disturbances, the so-called scorbutic leucemia, and it would seem impossible that in some cases at least that the absorption from the digestive tract may be the principal factor in the etiology. In answer to a question with regard to the long bones he said that in many cases they are affected, but the only way to determine this is by actual examination. In all blood diseases it would be advisable to examine the long bones, but unfortunately this is impossible, owing to social prejudice. In one case of chloroma where all the bones were examined, some greenish tumors were found in one femur, but not in the other. In answer to another question, Dr. Dock said that it seems not unlikely that a certain number of cases of chloroma have been reported as myeloma, that is tumors of the blood-making bone-marrow. Chloroma evidently gives the definite hint that there are several varieties of leucemia, which will have to be separated clinically, as well as by laboratory investigation, before this disease can be properly understood.

Types of Splenic Anemia or Splenomegaly.—Dr. Alfred Stengel, of Philadelphia, reported cases of enlargement of the spleen with some disturbance of the blood picture. The first case was that of a child three years of age with a rickety look but with very enlarged abdomen due to the presence of the large spleen. The patient succumbed to a complication and at the autopsy some miliary tubercles were found besides the very large spleen. In the second case an Italian suffering from a large spleen, which was thought to be malarial at first (he denied syphilitic infection) and there seemed to be no question of tuberculosis. He had a history, however, that pointed to the existence of the enlarged spleen for a long time and he was very much stunted in growth, with peculiar knobbing of the fingers and in general some serious disturbance of nutrition. In the third case a negress suffering from considerable discomfort because of the presence of enlarged spleen and splenic anemic as a complication had a history in which there was no malaria, though she came from a malarial district in the South and denied syphilitic infection. Her last two children, however, had been stillborn. Her condition became so severe that splenectomy was advised and there was at first some disturbance of the blood and later an absolute return to normal, which has been retained. The removed spleen showed a series of umbilicated more or less cicatricial pits but was very solid and was evidently invaded by some neoplastic formations. Under the microscope the picture presented was that of a large proliferation of the endothelial elements of the blood vessels of the spleen, giving the very characteristic appearance of primitive endothelioma of the

spleen. No tubercle bacilli could be found, no bacteria could be discovered by Gram's method. There were no signs of sporozoa and no necrosis of tissue in any part. The question whether it might not be syphilis must remain, though Dr. Stengel is of the opinion that it was not syphilitic. At the time of the operation it was noted that the liver was also wrinkled and had something of the dimpled appearance presented by the skin.

Lack of Vital Resistance.—This case exhibited a peculiar and very striking lack of vital resistance to infectious disease. She has suffered from parotitis several times, from pneumonia twice, from bronchitis and from other infections. There is always a low leucocytosis. This may indicate that disturbances of splenic activity are important factors in the production of the resistance to bacterial invasion, which is considerably more important than the virulence of bacteria themselves in the production of disease.

Complexity of Splenic Anemia.—Dr. Osler said that it must be clear to every clinician now that there is an extreme complexity of the subject of splenic anemia and that under the term are included a number of varying conditions. Some of these have a marked similarity to one another, but with distinctive features. Some of them are widely separated. The cases associated with nutritional changes, such as infantilism and clubbing of the fingers constitute one extreme. Dr. Osler has had under observation in recent years nine cases of large spleen. In one of these there was no other manifestation present except the physical discomfort of carrying around the enlarged organ. In four cases there was chronic splenic anemia with a reduction of the number of leucocytes, what would be called a moderate leucemia. Two cases were associated with liver symptoms and these need careful study and recognition as early as possible in order to use whatever prophylaxis is possible. These cases probably, bear some relation to Hanot's cirrhosis of the liver and deserve special investigation. There are evidently family forms of splenic enlargement, such as the type studied by Brill, in New York, in which an enlarged spleen could be traced in four generations. Dr. Osler is of the opinion that surgery can accomplish more for enlarged spleens than has been thought. When it is a source of discomfort the enlarged organ should be removed before it has contracted adhesions, or has seriously disturbed the patient's blood equilibrium.

Surgical Intervention.—Dr. George Dock said that it seems advisable to refer cases of enlarged spleen more frequently to the surgeon than is at present the custom. Whenever the hemic processes are negative then operation is indicated. Besides the relief of the patient's discomfort there is a decided advantage as regards our knowledge of the disease. If the spleen is allowed to remain, patients may live for years and other changes take place in the organ so that the autopsy gives a complicated picture and not the true idea of the condition in the spleen as it originally existed.

Movable Spleens.—Dr. B. W. Sippy, of Chicago, said that movable spleen, in women particularly, has in his experience been associated with gradual anemia. In one of these cases seen recently this anemia had reached the extent of two and a half million red blood corpuscles and forty per cent. of hemoglobin. There was a moderate poikilocytosis but there were no nucleated reds present. The spleen was removed and while there was a slight unfavorable reaction afterward, the anemia had decreased since and the patient has continued to be well. The enlarged organ showed only ordinary splenic hyperplasia with some endothelial overgrowth but not enough to stamp the process as true neoplasm and there was no involvement of the liver or lymph glands. The woman had not been a hearty eater for some time and it was possible of course that her lowered nutrition for this reason might have been the cause of her anemia. With regard to Dr. Sippy's presumption of the possibility of lack of nourishment causing anemia, Dr. Cabot, of Boston, said that there is no evidence at all of malnutrition ever causing anything like a true anemia. Lack of food affects other organs but not the blood-making organs apparently. The general statement then that undernutrition may play a rôle in these cases is always an undesirable one.

Philippine Anemia.—Dr. Osler said that among the cases of anemia that will be seen in soldiers who have recently returned from the Philippines there will probably be some cases in which the causative factor will prove to be the Donovan-Leischmann bodies. Many of these cases may be grouped under the heading of malarial anemia when this is really not the case. It is not difficult now to find faithful descriptions of the appearance of the Donovan-Leischmann bodies and there are even a number of specimens of them in the hands of the Marine Hospital Service. Physicians should not lose the opportunity then of getting at the true cause of these types of anemia and perhaps adding to our knowledge of the life cycle of this peculiar parasite.

Dr. Stengel, in closing the discussion, said that splenic enlargement is by no means necessarily associated with a serious pathological condition. It is perfectly compatible with ordinary good health. Cases that come present very different features and at one clinical lesson, not long since, he presented three cases with regard to which the conclusions as to treatment and prognosis were very different.

Cultivation of Trypanosomes.—That Frederick G. Novy, of Ann Arbor, Mich., said that most of the modern progress in bacteriology is due to the cultural methods for the growth of bacteria introduced by Koch. With regard to the more recent pathological organisms which have been brought to attention it seemed very desirable to find a culture medium or a series of culture media. In this country there is a trypanosome which affects rats quite commonly, which, after a series of observations, Dr. Novy has been able to make grow on a combination of agar and fibrinated blood. This does not grow directly on the medium itself but in the water of condensation or in the fluid material which is squeezed out of the agar blood serum mixture during the process of drying. He has now had some organisms which have in this way passed through thirty generations and after transplantation every month have remained alive for two years. These trypanosomes grow very well at ordinary temperatures. They grow faster in an incubator, but die out more rapidly at the higher temperature and have to be transplanted every week.

Living Culture Material.—While waiting to obtain fresh trypanosomes, Dr. Novy has employed inoculation into certain of the small animals as a method of keeping specimens sent him alive. The South African trypanosome may be grown upon the mouse.

The Lewis organism of this type may be grown on ordinary culture media and luxuriates almost as does the *Pneumococcus*. It has been kept alive for eighteen days in a test tube. Once Dr. Novy thought that he had succeeded in making the Bruce trypanosome to grow in this same way, but it proved eventually to be an ordinary rat trypanosome which had grown. These observations serve to show that these microorganisms are not, as has been thought, all of the same type but are very distinct.

Attenuated Protozoa.—Dr. Novy has found that these protozoa when grown at the room temperature may be quite virulent, even after passing through many generations in a test tube. If the test tubes, however, are kept at the temperature of 34° C. for two days while the microorganisms are quite active and reproduce very luxuriantly, being apparently perfectly healthy, yet they will produce no pathological effect. This is the first time that an attenuated form of protozoon has been found. With this modified organism an attempt was made to secure the protective vaccination of rats, but the animals proved too susceptible. Better success has been secured in this line with guinea-pigs and one of these animals has twice survived doses of trypanosome culture which killed the control animals in each case.

Different Forms of Trypanosomes.—The most important feature of present-day development of knowledge of trypanosomes is the conviction of the existence of a number of different forms. At first they were all thought to be the same. Laveran and Mesnil, however, showed quite distinctly that they were different organisms. This complicates the problem of disease but explains many anomalies that would otherwise be hard to understand and opens up a wide field for observation.

Survival of Philippine Trypanosomes.—Recently a medical man from Dr. Novy's laboratory went to the Philippines and under Dr. Novy's directions tried to send him specimen of the trypanosome which causes the surra disease. Ordinarily the blood of animals affected by surra loses its virulence, that is, all its power to reproduce the disease in about five days. Some of the blood is introduced into properly prepared test tubes, however, and after several trials a few of the tubes were found swarming with trypanosomes on their arrival. It took thirty-eight days for the journey, so that the problem of a culture method for this form of organism seems certain to be found. In these tubes one peculiarity was the existence of certain minute forms of protozoa which were at first considered to be so small as probably to lack virulence entirely.

Organisms That Passed Filters.—When an attempt was made to filter the smaller forms of organisms out of cultures the result seemed to be successful as far as the microscope was concerned, but when the filtrate was used for inoculation purposes, animals developed the disease. It seems clear then that very minute forms of the trypanosome, such as passed through Berkefeld filter, may still be capable of producing disease. Variations in morphology form one of the most interesting features of this new class of organisms. In the cycles of existence there seems to be a process of conjugation and then the organism may under certain circumstances divide into a large number of small trypanosomes. Some of these are really flagellate in character and this would seem to place them among the flagellate forms. This morphological peculiarity can perhaps best be understood by the realization of the fact that the spirillum of Obermeier, the well-known cause of intermittent fever, might very well be allied among these organisms under this form. It seems not unlikely therefore that these studies in the morphology of the peculiar protozoa, which the invasion of the tropics by the white man in recent years have brought more especially to attention, may well prove a source of suggestive information with regard to other causes of disease which are apparently better known, yet with regard to which our present knowledge is meager enough.

Zonal Necrosis of the Liver.—Dr. E. L. Opie, of Baltimore, read a paper on the peculiar distribution of various types of necrosis in the liver. The lesion is apt to be confined to certain zones leaving other parts untouched in such a way as to produce quite a striking pathological picture. There are three distinct zones of necrosis that he has had under observation, the peripheral on the outermost confines of the lobule, the central immediately around the central vessel and the intermediate, between these two areas. The intermediate is apt to be in connection with central necrosis more frequently than with peripheral and it is not unusual to find the whole lobule necrosed except for a thin peripheral boundary area where no trace of necrosis is present. These forms of necrosis mark out different parts in the lobule for special functions and it is the accomplishment of this function when toxic substances are present or bacterial invasion occurs that is the active cause of the necrosis.

Acute Yellow Atrophy.—Dr. Opie's studies seem to have shown him that necrosis in the intermediate zone of the liver lobule bears a special relation to acute yellow atrophy. In twelve instances of central necrosis, the lesion seemed to be associated with disturbances of the circulation complicated by infection. Median zone necrosis was associated with pregnancy and this lesion has been described by others as occurring in eclampsia. Out of five hundred autopsies this intermediate zone of the liver lobule was affected nine times. The source seemed to be ulcerative lesions somewhere in the digestive tract and severe digestive disturbances usually accompanied by infectious processes in the gastro-intestinal mucous membrane. In some cases of central and intermediate zone necrosis, where the outer narrow peripheral margin of the lobule was spared, the beginning of the lesion seems to have been in the intermediate zone. In the one case observed in which necrosis of the intermediate zone of the liver was not associated with eclampsia the patient had suffered from the pernicious vomiting of pregnancy. The beginning changes found in this case as well as in the others mentioned bore a resemblance to those which have been described at the beginning of acute yellow atrophy or icterus gravis, as it is sometimes called. It has been known for some time that while these cases are characterized by jaundice and delirium the liver is not always found atrophied. Liebermeister said that on the contrary if the patient dies before the ninth day of the disease enlargement is always found. If the affection continues after this and proves fatal the characteristic atrophy described by Rokitansky will be found. The essential feature is a necrosis with fatty degeneration.

Liver Infections.—In a certain number of cases the typhoid bacillus has been found in livers suffering from acute necrotic conditions. In others the streptococcus has been found. As might readily be expected, in these cases a fatal issue has occurred before the stage of acute yellow atrophy had time to occur. It would seem, however, that this condition is always due to infectious material absorbed from the digestive tract, usually from ulcerative lesions of the digestive tract, producing serious effects in the intermediate and central zones of the liver lobule. Marchand has suggested that regenerative changes in the liver take place either from the center or the periphery; where the infection that causes the tendency to necrosis is not very severe, such regeneration may save the patient.

Malignant Adenoma of the Liver.—Dr. George L. Peabody, of New York, presented the specimens from a case of malignant adenoma of the liver. The patient was a Greek, thirty-eight years of age, who denied syphilis and alcoholism. Two weeks before his admission to the Presbyterian Hospital he began to suffer

acutely from ascites. The symptoms were a sense of weight and a difficulty of respiration. Shortly after his admission to the hospital he was tapped and 7½ liters of fluid were removed from his abdominal cavity. This fluid was a bloody serum so hemorrhagic in character as to look like slightly diluted blood, rather than blood-colored serum. A smear looked like blood. The patient was relieved very much but his ascites recurred again after a few days and he had to be tapped once more. Before the tapping the liver and spleen could not be made out by palpation because of the tension of the abdominal walls due to the fluid. On percussion both the organs seemed to be smaller than normal. After the removal of the fluid neither the spleen nor the liver could be felt, but there was no doubt that both were very much decreased in size. After several tappings the man gradually succumbed with some of the symptoms of cachexia and it was concluded that he was suffering from malignant disease.

Autopsy Findings.—At the autopsy an irregular mass was found projecting on the upper surface of the small hard liver. The lymph glands in the upper part of the peritoneal cavity, in the mesentery and also some of the bronchial glands were found enlarged. There was thrombosis of the large veins of the liver itself and of the spleen. The liver was very much reduced in size and was covered by a number of cicatricial-like puckerings that inevitably suggested syphilis. The liver was irregular from contraction, but also because of the presence of a new growth irregularly infiltrating its tissues. This was of the so-called tubular or trabecular variety, such as is sometimes called adenoma. It consisted of modified liver cells, the larger ones containing two or more nuclei. There were no metastatic growths to be found anywhere, though some of the vessels of the liver were filled with tumor masses.

Usual Occurrence in and Course.—Liver adenoma usually occurs in connection with cirrhosis and is not often seen except in men. In them it is commonest about the age of forty years, rarely in patients beyond that age. It seldom takes more than a few months to bring about a fatal termination. One of the most prominent symptoms is ascites, which reaches a large amount. This fluid is nearly always discolored with blood because there is usually a leakage from some of the vessels of the tumor. In this case it is not difficult to see on the specimen whence the blood came which caused the hemorrhagic serum to have such a bloody tinge. Jaundice is another very common symptom in these cases, though not always present. When a large ascites develops rapidly and the tapping shows the presence of considerable blood, suspicion must always be aroused as to the malignant character of the affection. The clinical picture, however, is in general not unlike that presented by secondary carcinoma.

The Adrenal in Addison's Disease.—Dr. Charles F. Withington, of Boston, discussed the reported cases of Addison's disease and their relation to adrenal tuberculosis. While tuberculosis of these glands is the most common cause of Addison's disease, it is by no means the only one and a number of cases have been noted without any adrenal tuberculosis. In the non-tuberculous cases the lesions found were atrophy of the adrenal glands, interstitial inflammation, cancer, occlusion of the veins of, or hemorrhage into the adrenal structure. In a certain number of cases no disease of the adrenals was found at all. In some of these a lesion of the semilunar ganglion was found. In some others this lesion was not present. In a certain number of cases a pigmentation resembling that of Addison's disease was observed but without any proper warrant for considering the disease Addison's disease.

Atrophy of Adrenals.—In one case reported there was a curious pigmentation that occurred on the backs of the hands and in the axillæ and very markedly in the pits of smallpox on the face. The pigment was dark bronze in color. No pathological lesion of the adrenals was found but there was very distinct atrophy of both these glands. In a certain number of cases of Addison's disease reported the adrenal glands have been found to be very small or one of them has been missing and the other not especially large, but in these cases the possibility must always be remembered of there being adrenal tissue elsewhere to make up for the apparently absent adrenals. Adrenal elements in the kidneys or in other organs or in structures in the neighborhood of the adrenals is not at all unusual and these strayed elements sometimes become the basis for very serious and fatal malignant tumors.

Function of Adrenal.—It is now generally conceded that the symptoms of Addison's disease are due to loss of function on the part of the adrenal glands. The substance which enters the blood from the adrenals and which is necessary for the preservation of the tone of muscles and especially of the muscular coats of the blood vessels is considered to be a secretion rather than an excretion. Something is added to the blood not something taken from it during its course through the adrenal glands. There is no doubt now that adrenal secretions have an influence over even voluntary muscles and this accounts for the marked weakness which is so often seen early in the disease before the affection would seem to have spread far enough to justify the languor which comes over the patient.

Experimental Arthritis and Endocarditis.—Dr. Morris Lewis, of Philadelphia, read a paper describing some recent experimental observations in the production of arthritis complicated by endocarditis in animals by the injection of a culture of a special form of streptococcus. This streptococcus had been found in a case of severe chorea which developed after an attack of acute rheumatic arthritis in a girl. The girl had complained first of pain and a swelling of the ankles and the disease being recognized as acute rheumatism, she was put to bed where she rapidly improved under the salicylate treatment. After a time, however, she became languid and was treated with quinine without success. Then she began to develop choreic movements which finally became so severe that she could not swallow except with difficulty and the sides of the bed had to be padded. When brought to the Infirmary for Nervous Diseases in Philadelphia she was very limp from her journey but still had some choreic movements. When she recovered from her fatigue her choreic movements became more marked and after several days endocarditis developed. This ran a rapid course. Cultures were taken from the median basilic vein as it proved only twelve hours before her death. In this blood, taken with all due aseptic precautions, a streptococcus was found. Cultures of this microorganism, when introduced intravenously into animals always give rise to arthritis which developed after an incubation period of from four to nine days. The animals would not move for some time before swelling could be noticed and it was evident that they were suffering somewhat in their joints, even before marked signs of arthritis developed.

Complicating Endocarditis.—In several of the animals an affection of the heart occurred which was of vegetative character. In nearly all the cases there was a spread of the arthritis from one joint to another after the first symptoms of the affection had developed. The streptococcus found in the blood culture could be isolated from all the affected joints of the animals. In

one of the rabbits it was also found in the vegetations on the heart valves. This streptococcus could not be distinguished morphologically or by any of the ordinary culture methods from the streptococcus which is commonly studied in the bacteriological laboratories. It seems to Dr. Lewis that the organism thus found is the same as has been described by certain observers in Germany and by certain English authorities in the bacteriology of rheumatism. It would seem to fulfil all the requisites demanded of a specific microorganism. It is found in the blood of a person suffering from the disease; it can be isolated in pure culture; it can be injected into animals and reproduce the characteristic symptoms of the original disease and then, finally, and most important, can be isolated in its original form from the affected tissues of the animals experimentally inoculated.

NEW YORK NEUROLOGICAL SOCIETY.

Regular Meeting, March 1, 1904.

The President, Pearce Bailey, M.D., in the Chair.

A Case of Facial Hemiatrophy.—Dr. Pierce Clark, who presented this paper, said he was indebted to Dr. McEntee for the history of this case, and to Dr. Holding for the X-ray pictures. The details of the case were as follows: The patient was a man, sixty-two years old, married, and the father of two children. His occupation was that of a clerk. His family history was negative. The patient himself had never had any serious illness. As a boy of five or six years, he received a slight burn on the right side of the face, which, however, left no scar, and the occurrence of which slipped his memory during the first two or three examinations. Eighteen years ago, at the age of forty-four years, the patient noticed a slight muscular contraction in the right side of the neck under the jaw, similar to that which was now present in the masseter and temporal muscles. The muscular twitchings were probably in the digastric and pterygoids. Rubbing diminished the spasm for a time. There was no pain; only discomfort, to which he soon accustomed himself. After three or four years he noticed the twitching or fibrillations now present. The tremor ceased at times, but quickly returned on fatigue, exposure to cold, excitement, or any undue emotional stress. About six years ago he noticed the wasting in the right side of the face. Three years ago it became very marked, the teeth became decayed and loose and were easily removed by a dentist. Early last January he contracted right trigeminal neuralgia in all three distributions of the nerve, from which he was now slowly recovering. The physical examination showed that all the cranial nerves were free with the exception of the fifth. The sensory portion appeared intact, with the exception that differential smell and taste were a little slow on the right side, possibly due to the functional defect expressed in the neuralgia. The atrophy of the skin, subcutaneous fat and bone were sharply confined to the supposed distribution of the fifth nerve. There was no defect in the palate or tongue. There was no atrophy nor reaction of degeneration in the motor portion of the fifth nerve, the fibrillation being the only evidence of the involvement of the masseters and temporal. There was, however, a shortening of the masticatory muscle, which apparently restricted the separation of the jaws about one inch; this limitation was described in the absence of fibrillation so that he could do a little better than this, particularly in the morning, after a full night's rest. There were no lateral movements of the jaw, the pterygoids, apparently not functionating. The amount of asymmetry in this case was not so great as in those cases occurring in earlier life, where a hindrance of growth increased the effects of wasting. The atrophy had always been general, and not especially marked in any one spot, as in the facial hemiatrophies of sclerodermal origin or of the morpheal type. The hair and beard did not participate in the affection, although there was a rather marked thinning and whitening at the free border of the hair on the right side of the forehead. The lesion seemed to affect all divisions of the fifth nerve, and was not entirely confined to the right side.

Dr. William M. Leszynsky said that the patient had developed a trigeminal neuralgia on the affected side of the face. The speaker said he had seen several cases of facial tic where subsequently a trigeminal neuralgia developed on the same side.

Dr. Pearce Bailey called attention to the long duration of the hemiatrophy and said that the marked fibrillation was rather suggestive of the analogous condition observed in progressive muscular atrophy.

Dr. J. Ramsay Hunt said he did not see how Dr. Clark could exclude a slowly progressing lesion of the fifth nerve. A slowly growing tumor would account for the neuralgia, the hemiatrophy and fibrillation, and the muscular contractions in the masseter and temporal. The speaker said he thought the sensory symptoms excluded progressive muscular atrophy.

Dr. Clark, in closing, said the analogy between his case and one of progressive muscular atrophy did not go further than the fibrillation. There was no evidence of progressive loss of power in the masseter and temporal muscles. If the lesion suggested by Dr. Hunt was a tumor, it must be a very slowly progressing one, as the condition had existed for eighteen years. Possibly it had to do with the motor division of the nerve only. Slowly progressive alterations in the posterior root ganglions were very likely to be attended with trophic loss without changes in the pain or tactile sensations.

Dr. Clark also presented some X-ray photographs to illustrate an easy clinical method of demonstrating volumetric hypertrophy in bone, muscle and fat in parts which undergo true or false hypertrophy. It obviated the necessity of excising tissue, which was a painful and inaccurate means of determining these alterations, although the latter method must be resorted to in order to determine whether the muscular increase was due to hyperplasia or fiber hypertrophy. The photographs were of a case of hypertrophy of the leg of the paralyzed side of an infantile cerebral hemiplegia. The X-ray negatives were made by Dr. Holding.

A Case of Idiopathic Epilepsy in a Canary Bird.—This case was also reported by Dr. Pierce Clark. The bird was a male, one year old, from a brood of four. The family and personal history was negative. No cause for the epilepsy was known. Typical idiopathic *grand mal* of Jacksonian onset, and *petit mal* occurred irregularly every few days at the beginning of the observation period. After giving a detailed description of the attacks, Dr. Clark said the case was interesting because it showed (1) apparent idiopathic epilepsy in a bird. Nearly all previously reported cases of animal epilepsy, and especially in the bird, where an autopsy was made, proved to be Jacksonian traumatic epilepsies; (2) postepileptic exhaustion paralysis; (3) status epilepticus and death analogous in many clinical respects to that seen in the human.

A Case of Cerebral Tumor, with Specimen.—Dr. Clark reported this case, in order to show the absence of localizing symptoms, particularly astereognosis, which one would expect to be present from the nature, size and position of the tumor. The history of the case was as follows: S. B., aged thirty-six years, a housewife, married two years. A native of Hungary. Her

family history was negative, and she had always enjoyed good health until eighteen months ago, when she began to complain of postoccipital paroxysmal headache, which was especially marked on the left side and extended down into the corresponding shoulder. Six months later the attacks of headache were accompanied by vomiting. On August 13, 1903, one year after the onset of her symptoms, an examination was made which showed that there was no cranial nerve involvement excepting the optic nerve, the power of which was impaired, and in November the patient became completely blind. There was no astereognosis in hand or foot. There were no focalizing symptoms excepting the persistent pain over the left parietal region, which was increased on pressure and accompanied by stiffening of the muscles on the left side of the neck. Inasmuch as the patient became delirious at times from the headache, and as the X-ray negative showed a light shadow approximately in the region of the pain and tenderness, it was decided to make an exploratory incision, which was done by Dr. Hartley, at the New York Hospital on January 20 last. There was considerable bulging in the trephine opening, but the operation failed to disclose the tumor. However, it relieved the patient of headache and all her distressing symptoms. The swelling disappeared from the optic disk and the nerve showed complete atrophy. Three weeks after the operation the patient disturbed the dressing, which she said irritated her scalp. In consequence of this the wound became inflamed, and death resulted on February 24. The autopsy was performed by Dr. Biggs, who found a tumor deeply imbedded in the posterosuperior part of the right parietal lobe. It was round and firm and attached to the neighboring portion of the falx. It was about 4½ cm. in diameter; anteriorly, its border corresponded to the termination of the collosomarginal fissure, and posteriorly it extended to within one centimeter of the parieto-occipital fissure. The probable diagnosis was an endothelioma of the dura.

A Case of Myasthenia Gravis Pseudoparalytica (?).—This was presented by Dr. B. Sachs. The patient was a man aged thirty-five years; a picture-framer by occupation. He had had typhoid fever in childhood, and when he was sixteen years old he had an attack of St. Vitus dance which lasted about four months and was very severe. Five years ago he had pneumonia. Between the ages of sixteen and thirty years he was, comparatively speaking, a well man. In April, 1902, he stated that his tongue felt very heavy; this lasted about six weeks and then passed off. On February 1, 1903, he received a glancing blow on the head with a sharp knife. The knife, which was about 40 inches long and weighed fully 75 pounds, was attached to a table above his head, and came down full force, although it only caused a slight wound which readily healed within a week. In September, 1903, his tongue again began to feel heavy and he became very nervous. At times he did not have the use of his tongue at all. The first examination of the patient made by Dr. Sachs revealed a peculiarity of speech, which was thick and distinctly bulbar in character. The head was inclined forward, and to the right side. He also complained of weakness in his hands, and said he could not do his work properly. Formerly, he had been able to cut through many thicknesses of cardboard easily, but now he did not have the power to draw the knife through. There were no signs of paralysis, but he did not have the grasp of an able-bodied man. He complained of becoming tired after slight exertion. At the time of the first examination, the knee-jerks were absent. Since December 5, 1903, when Dr. Sachs first saw him, there had been a distinct improvement in his speech and general condition. He complained that his vision was at times limited, so that he could not look up well. While using a knife or fork he occasionally halted in the movement for a moment, showing that the effort to use his muscles was at times ineffectual. Since the first examination the knee-jerks had returned and were normal. Another symptom of which he had complained was difficulty in swallowing; food would at times produce a choking sensation and there was occasional regurgitation. He had also complained of drooling. He never had any trouble in chewing his food. There was no fibrillary tremor of the tongue; electrical examinations were negative. Heart and lungs and other organs were apparently normal. The reflexes were not increased. There was no atrophy anywhere, either in the shoulders or upper or lower extremities. Dr. Sachs said he had examined this patient frequently, and the case had puzzled him greatly. The diagnosis had been still further obscured by the fact that the patient had been thoroughly mercurialized, and his gums had become affected. This was also the cause of the drooling. Among the conditions considered were a recurrence of the chorea, with thickness of speech, and amyotrophic lateral sclerosis, but the symptoms did not warrant either diagnosis. There was nothing to indicate the bulbar form of muscular atrophy, and Dr. Sachs said he finally came to the conclusion that the case represented an atypical form of myasthenia gravis pseudoparalytica.

Dr. Bailey said that in the cases of myasthenia gravis he had seen the muscles become easily fatigued. This applied not only to the voluntary muscles, but to the reflexes.

Dr. Hunt said the symptoms in the early stage of the case, as his diplopia, paresthesia of the tongue and absent knee-jerks were rather suggestive of tabes. Dr. Spiller, of Philadelphia, had reported such a case of bulbar tabes about a year ago, in which there was difficulty in deglutition and articulation. The improvement in the symptoms may have been due to the mercurialization; such retrogression in the earlier stage was not uncommon.

Dr. Sachs said that when he first saw the case he was inclined to regard it as an example of the bulbar form of tabes, but he had since been compelled to abandon that diagnosis. The knee-jerks, which were at first absent, had returned. There had never been any lightning pains nor eye-symptoms, nor other evidences of tabes.

A Case of Multiple Neuritis. This case was presented by Dr. Isador Abrahamson. The patient was a woman, who was born in Germany thirty-four years ago. With the exception of an attack of pleurisy three years ago, her personal history was negative. Her present illness dated back to February, 1903, when she noticed some weakness in the legs, especially the right one. In March she had an attack of cough, with expectoration and pain, especially over the left shoulder-blade, and her attending physician told her she had a recurrence of her pleurisy. Three or four weeks later she had an attack of vomiting and diarrhea, with edema of the face and all four extremities; the latter symptoms were not marked; there was some fever. The urine was negative. A "leaky heart" was diagnosed by her physician. She now began to complain of pain chiefly at night; it was boring in character, involving the outer sides of both legs. There were no local signs excepting tenderness on pressure along the outer surface of the legs. The pains and weakness in the legs progressed, and four weeks later she began to complain of numbness in the hands, especially the right, with beginning weakness on the thumb side more than on the ulnar. There was noticeable wasting in the legs, chiefly on their outer surfaces, and paresthesia in the region of the thighs, legs

and feet. During all this time the patient remained in bed, suffering from frequent urination and diarrhea. Her fever lasted about two weeks. The diagnosis made at this time was influenza. Upon attempting to leave her bed, she found that she was unable to walk. Dropped feet were apparent, and to a lesser extent dropped wrist. The physicians in attendance called the condition neuritis and partial muscular paralysis. According to their statement, no sensory disturbances were present. The patient stated that she felt at all times the slightest touch, and that she was able to distinguish pin-pricks and hot and cold applications. She felt acutely the application of the faradic current. She was seen by Dr. Rieser on October 1, 1903, who found no sensory disturbances, although multiple neuritis of influenzal origin was diagnosed. The case was referred to Dr. Abrahamson on October 26, 1903. At that time some improvement had already taken place. There was marked motor weakness in both forearms and hands, and some wasting of the right thenar eminence. There was partial dropped wrists on both sides. The deep reflexes were absent; there was some ataxia, chiefly on the right side. The greatest weakness was in the extensors of the forearm; in the flexors of the hand and in the pronators and supinators. No sensory disturbances could be elicited. The heart was apparently normal and the trunk muscles intact. The abdominal reflexes were present.

There was a distinct dropped foot, and the patient walked very unsteadily. There was some wasting of the peronei muscles. There were no fibrillary twitchings. The knee-jerks and Achilles reflex were absent on both sides. The feet were cold and somewhat congested. There was tenderness along the perineal nerve; less along the posterior surface. Decided reaction of degeneration in peroneals. With the exception of slight tactile uncertainty, occurring only at times and not at all constant, there were no changes in tactile, pain or temperature sensations. The patient was treated with electricity and strychnine and improved rapidly. She was now able to walk alone, although there was still some peroneal weakness. In view of the history of edema, diarrhea and vomiting, the distinctly peripheral character of the paralysis, the paresthesia, pain, nerve tenderness, etc., and the rather slow but progressive character of the onset left little doubt as to the diagnosis, in spite of the absence of objective sensory symptoms. Landry's paralysis, the speaker thought, could be excluded, though there were many points of resemblance. The etiology of the multiple neuritis, upon careful examination and questioning, negatived any metallic poisoning, and influenza had to be assumed as the etiologic factor. A few similar cases had been reported by Bloeq and others.

Dr. Sachs said if there was one fact that had been learned about multiple neuritis, it was that for some reason which it was difficult to explain sensory symptoms were almost invariably less prominent than the motor. He considered the motor form of multiple neuritis infinitely more common than the sensory. In the earlier stages of the disease there was usually some sensitiveness to pressure over the nerve, but actual objective sensory symptoms were frequently absent in the most pronounced and indubitable cases of multiple neuritis.

Dr. Leszynsky said he agreed entirely with Dr. Sachs. In several cases of multiple neuritis, however, he had observed slight sensory disturbances in the early stages, which disappeared within a few weeks. In the later stages of the disease he found no sensory symptoms whatever.

Dr. Clark said he had seen a number of Barnes' cases in London, and listened to a discussion upon them. They distinctly represented a form of polyneuritis, involving the motor fibers of the nerve almost exclusively. In the course of the discussion, one of the speakers said he doubted whether there were any cases of purely sensory neuritis.

Dr. Abrahamson, in closing, said this was the only case of multiple neuritis he had seen that had not shown at any stage the least objective disturbance of sensibility.

A Case of Recurrent Peripheral Facial Paralysis.—This case was also presented by Dr. Abrahamson. The patient was a man, thirty-two years old, a hatmaker by occupation. His family history was negative. Six months ago a physician who examined him for a lodge found albumin in the urine. Denies syphilis. He used alcohol and tobacco in moderation. He stated that in the preparation of the felt for hats, mercury and probably arsenic was used for shrinking purposes, and that many of his fellow-workmen exhibited tremor and salivation. Personally, he had never shown any symptoms of mercurial poisoning. The patient's symptoms were those of peripheral facial palsy, of which this was his fourth attack. His first attack was on the right side, and occurred sixteen years ago, all three branches of the nerve being involved. The attack lasted three or four months. His hearing remained normal; there was no otitis. The attack was attributed to exposure. He made a complete recovery; there were no sensory symptoms. His second attack occurred four years later. It was on the left side and all three branches of the nerve were involved. It lasted about the same length of time as the first. There was no otitis; no sensory symptoms. Recovery was complete. The third attack was also on the left side, and occurred seven years ago. All three branches of the nerve were involved. There were no aural symptoms. The attack lasted four months; recovery was complete. His present attack dated back to February 3, 1904. It began with pains radiating from the left aural region to the left lower face, and was followed by paralysis of all three branches of the left facial nerve. Hearing was not impaired; there were no evidences of any otitis. The patient also complained of some weakness and a cramp-like feeling in the left hand, especially when grasping objects. There was no headache, vertigo nor vomiting. His mentality was not impaired. There was no difficulty in swallowing, speaking, etc. Micturition and defecation were normal. He had never had diplopia. Examination revealed a paralysis of all three branches of the facial nerve. The tongue was drawn slightly to the right; the uvula markedly so. Taste was impaired over the left half of the tongue. Hearing was not impaired. The ocular movements and superficial reflexes were normal. There was no ataxia. No evidence of lues. The sensibility, especially to temperature, was markedly diminished over the left half of the body, excluding the genitalia.

Dr. Abrahamson said the case was particularly interesting on account of the multiplicity of the attacks. As to the cause of the attacks, syphilis was apparently negatived by the absence of any history or findings indicating that disease, the vague nature of the ophthalmoscopic findings (which upon second examination were negative), the completeness of the facial palsy each time, the absence of involvement of any other cranial nerves, and the completeness of recovery without specific treatment. As to the cause of the attacks, mercury, with or without arsenic, was possibly the true etiological factor. The associated hemianesthesia was no doubt of a hysterical nature.

Nervous Symptoms in Three Patients with Azoturia.—Dr. William H. Thomson read a paper on this subject, in which he stated that it was his routine practice with all patients who consulted him for nervous

ailments to have frequent examinations made of the urine for the purpose of determining the daily output of its *normal* ingredients. Repeatedly, in many cases of so-called neurasthenia, the reports would show that the excretion of urea would be only from one-fourth to one-half of what it ought to be, with sometimes a corresponding diminution of the other solids of the urine, and sometimes not, but rather an excess of the other saline ingredients, with a marked diminution of urea. Occasionally, however, he has had patients narrate a series of symptoms resembling in many particulars those showing deficiency of elimination, but on examination they proved to have a marked excess of both urea and solids amounting in one case to ten times the quantity of urea of another patient who clinically might have been classed with him as a typical neurasthenic. To illustrate this condition, Dr. Thomson briefly reported three such cases coming under his observation. In all three of these cases, pain in the eyes, especially from reading, was a leading symptom. What connection there could be between their ocular troubles and the marked excess in the excretion of urea and of other solids he could not say, and he was inclined to look upon their occurrence as accidental. His own view about the nature of these cases was that they were related to diabetes mellitus, and he would term them urea diabetes in distinction from saccharine diabetes. He did not venture to guess what the underlying cause of this particular form of systemic waste could be, but following his hypothesis, he laid down for these patients the same line of treatment which he would for a diabetic. His notes showed that these patients could not digest starches, and for that reason he largely excluded farinaceous articles from their diet and then prescribed the antiseptics which he had treated of more fully in a recently published paper on the Medical Treatment of Diabetics. Dr. Thomson said that in none of his three cases were the patients large meat eaters. The first patient said she could not eat meat with any comfort, and rarely touched it. The second patient said she had given up beef and mutton some years ago because it usually gave her a headache. The third patient was almost an anchorite and was practically starving himself, as he believed that his stomach was the cause of all his troubles.

WILLS' HOSPITAL OPHTHALMIC SOCIETY.

Stated Meeting, held March 14, 1904.

The Chairman, William Zentmayer, M.D., in the Chair.

DISCUSSION UPON GLAUCOMA.

Glaucoma.—Dr. Frank Fisher, in order to open the subject, cited the histories of two diametrically opposed types of such cases which had recently come under his observation. He desired to know under what conditions an iridectomy should be performed; when should enucleation of a glaucomatous blind eye be done; and if enucleation be done, what effect would the procedure have upon the fellow eye. He was uncertain as to the character of the visual fields serving as a guide to the value of an iridectomy, they being so unstable and uncertain. His experience had led him to ignore the usefulness of the degree or the grade of visual acuity as offering itself as a therapeutic guide. In some eyes which had become blinded from glaucoma processes, he had found that eserine failed to produce pupillary contraction. He had been interested in studying a series of cases of glaucoma, in which there had not been any consanguineous marriages: he gave the detailed history of one such family, and had more or less knowledge of some others. He inquired what had been the experience of members of the society in regard to the ophthalmoscopic appearances of the eyeground and media after the performance of posterior sclerotomy. He asked this question as he had seen two cases in which he could locate the position of the internal traumatism by a localized rupture of the chorioid. He would like to know the most tenable theory for the more or less reduction of intraocular tension in cases in which posterior sclerotomy had been done. He asked the question whether the vitreous elements were reformed or not. He would like to know if any members of the society had, like himself, seen recession of optic nerve head cupping after successful iridectomy.

Enucleation and Iridectomy.—The chairman stated that he enucleated the offending eye in absolute glaucoma, with a possible previous attempt at iridectomy. He performed an iridectomy, if possible, in acute inflammatory glaucoma. His studies with the visual fields in chronic glaucoma had taught him that the character of decreases and the peculiarities of lessened areas were not in any way characteristic or typical.

Remedial Measures.—Dr. Conrad Berens believed that enucleation tended toward the conservation of the energies of the other eye; his experience being that vision and intraocular tension of the remaining eye are preserved for much longer periods of time. His experience had taught him that the earlier an enucleation is done—particularly in a painful eye—the safer it is for the other one. If possible, he preferred an early iridectomy in all appropriate cases. In some cases of systemic type he eschewed all forms of operative procedure and preferred to wait for some acute condition necessitating radical measures, watching and guarding over the general system, and directing his main therapy toward the general dyscrasia at hand. He had found good results from the ingestion of large doses of iodide of potassium in association with the salicylates. He had found that the more he had to deal with the condition, the more he depended upon remedial measures, reserving, as a rule, operative interference for cases of the fulminating type. He had observed the effects of climate upon such cases, and spoke of the effects of psychological processes upon the condition of the patient. He mentioned his experiences with the results that he had obtained in some of his chronic cases by the employment of varying strengths of synoidal currents.

Dr. McCluney Radcliffe showed a case under his care in the hospital in which by enucleation of the blind eye, in combination with appropriate local and general treatment, the ordinarily seen progressive and disastrous symptoms, he felt sure, were rapidly and painlessly disappearing in the fellow eye.

Removal of the Crystalline Lens.—Dr. Charles A. Oliver said that no fast and hard law could be laid down in any particular case. Each one, and even the same case at different times, demanding what might be aptly termed "symptomatic treatment." After a large experience with various operative measures, in association with carefully graded local and general therapy, and above all, hygiene with well-regulated cheerful surroundings, and early treatment directed toward the removal of any possible offending dyscrasia, he had in many cases, ceased to be disturbed as to the probability of ultimate failure; in other words, he made it an unalterable rule to exercise constant vigilance against the general and special inroads of any causative factor with the prompt removal of the disturbing local conditions in the easiest and the most conformable way possible in each case. Whenever possible, he enucleated an eye which had become blinded from glaucoma, as he had learned from experience that it was the safest and the most certain of all of the radical procedures

in certain types of cases for the good of the fellow eye; in fact, he was certain that it undoubtedly seemed to have a beneficial influence upon the fellow organ, whether it was injured or not. The question of the performance of an iridectomy he reserved to cases in all stages, more particularly the incipient and practically unadvanced ones in which he felt that there was either a present necessity or an advantage in the future to be gained by opening as much as possible of an imperfectly acting filtration angle. In some cases of coarse severity, he repeated the iridectomy and even had successfully and usefully removed the crystalline lens. He uniformly reserved his operative procedures to the individual organ in question. He spoke of having seen some cases in the hands of some of his colleagues apparently do well by the employment of cyclotomy, and believed that the measure, if not too disturbing in its immediate traumatism, possibly did good by destruction of some of the lymph making glands. He asserted his disbelief in a proper regeneration of the vitreal elements, believing the vitreous to be like the crystalline lens, an organized body, which once removed or destroyed, was replaced with ordinary lymph: in consequence, he doubted the efficacy of all procedures in which loss of the vitreous body constituted a part. He denounced the term "liquid or fluid vitreous," and said that the replacement of the vitreous humor by ordinary lymph in which there were loose vitreal elements with uveal débris merely tended to provoke glandular action with consequent increase of the intraocular fluids. He spoke of the classical experiments of Uribe Troncoso upon the effects of altitude upon the density of the intraocular fluids, as well as the morphological conditions of the fluids themselves. As one of the results of a return of intraocular pressure to normal, he had more than once seen temporary lessening and even disappearance of shallow pathological cuppings in the optic nerve head, particularly in the temporally placed finer fibers.

Posterior Sclerotomy.—Dr. S. Lewis Ziegler spoke of the advantages and the good results he had personally obtained in certain varieties of cases by the performance of posterior sclerotomy. He made the procedure by a quick plunge with a von Graefe knife with its back directed toward the ciliary body some six or eight millimeters back of the ciliary region, between the muscular attachments, and parallel with the radiating vessels. He rotated the knife at right angles to the first incision, allowed a few beads of vitreous to escape, and withdrew the instrument, thus making a T incision. He had found that there is immediate hypotension and there is never any reaction. His experiences had coincided closely with those given by Dr. Oliver. In the blind eyes of some such types he had had useful recourse to opticociliary neurotomy, having, he remembers in more than one instance, kept a functionless eyeball intact and free from pain and harmful influences for a period of nine years. He mentioned several interesting examples of the various conditions, showing the multiplicity and variability of the symptom-complex in cases which had come under his immediate observation; distinctly proving the efficacy of certain procedures in some cases, and the inefficiencies of many authoritative measures that had been strictly applied, in others. The more extended his experience had become in such an enormous mass of material as was almost daily given him in such a large service as in the outpatient department of the hospital, the broader and the more conservative had become his views in regard to therapeutic measures. He was daily waiting for opportunity, and was more than willing to apply any plan of therapy which offered in the least a greater chance for the patient's welfare. Upon being asked whether he would do an iridectomy at the time of the appearance of the earliest signs and symptoms of the disease, he answered that he would in appropriate cases. He had never had any intraocular complications of inflammatory type to arise after the performance of posterior sclerotomy. In a number of painful cases in which immediate operative procedure could not be done, he had most useful recourse to a formula containing hyoscine, hydrobromate, morphine, strychnine, and pilocarpine; a combination which not only subdued pain, but which both stimulated and controlled lymph circulation. In support of his claim for the value of these therapeutic agents, he cited three most interesting confirmative cases which he had seen at the hospital several years previously. In the use of electricity he had had considerable experience, finding a most curious paradoxical result that pain and tension are reduced when the negative electrode is applied to the eyeball. In his hands, pneumo-massage had given but moderate effects in some cases of chronic glaucoma.

NORTH BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, held Thursday, April 14, 1904.

The President, Samuel Wolfe, M.D., in the Chair.

Some Reflex Conditions Caused by Foreign Bodies in the Intestinal Tract.—Dr. Anna M. Reynolds read this paper. The first case was that of an infant six months old, taken suddenly ill in the morning with diarrhea followed by vomiting, which was diagnosed on the fourth day as caused by the uterus pressing on the bowel. The next day several hard convulsions occurred resulting fatally and the condition was found to be impaction of the bowel. The second case was a female, aged fifty-two years, who began with convulsions when a baby, two years later developing epilepsy, for which she was treated by a German doctor by means of large doses of calomel and castor oil and for about twelve years filled a responsible position. Another case which was diagnosed as extrauterine pregnancy proved to be a mass of blackberry seeds. The fourth patient was a male infant who began with bilious attacks, which increased in frequency and finally he lost consciousness; the case was diagnosed as epilepsy. Upon the administration of half a grain of calomel every hour for six doses followed by castor oil, a brass button with a shank was passed, which he had lost off his coat and the convulsions ceased. The fifth patient was subject to constipation and dizzy spells and one morning had two in succession. Calomel and castor oil and liquor potassium arsenitis were administered and in two years there has been no return of the symptoms. The sixth case was that of a young man who had convulsions at the age of three years and at twenty-four developed epilepsy. He was treated by the bromides with no success, after which he went to the country and gave careful attention to his diet and bowels, and has had only two very light seizures in four months.

Dr. Boardman Reed believed that there were a great many more conditions resulting from reflex symptoms of the intestinal tract than is usually recognized, not only epilepsy, but also headaches, nervousness, etc., and that even true epilepsy was much aggravated by disturbance therein, and recommended thorough daily evacuation of the bowels.

Dr. William H. Good referred to the case of a woman who was troubled with hoarseness which disappeared after the expulsion of a large amount of worms.

Dr. Mordecai Price referred to a case of epilepsy

which had been under his care for a year, in which the bromide treatment had been of no avail; upon cessation of the treatment the symptoms cleared up.

Dr. Frank White referred to two cases as illustrating the tolerance of the intestinal tract without producing reflex symptoms in some cases. In the first, a foreign body, 5½ inches long by 1½ inches in thickness and weighing 4½ ounces was removed from the stomach of an idiotic boy at autopsy; and in the other case about 15 whole shellbarks and about half as many in pieces were removed from a boy's rectum. In neither case were there any reflex symptoms.

The Surgical Treatment of Abortion.—Dr. Frank C. Hammond read this paper. He stated that it was always desirable to ascertain when threatened abortion becomes inevitable, as the treatment will be thereby radically altered. He called attention to the fact that hemorrhage more or less persistent might exist, even during the entire period of pregnancy, without producing an abortion. He cited the cases observed by Playfair, Charpentier, Doloris and others, in which pieces of decidua were expelled without the interruption of pregnancy. When the abortion is inevitable, the chief dangers are from hemorrhage and septicemia, either general or a local infection. Tetanus occasionally follows abortion. Suspicion should always be directed to every case resembling acute articular rheumatism, following a recent abortion, as it is much more likely to be suppurative arthritis, which should be treated by free incision and drainage, strict antisepsis being observed. The remote dangers from abortion are inflammatory disease of the uterus and adnexa, with the resultant train of pelvic and reflex symptoms. He reported a case in which two Italian physicians had diagnosed malignant uterine disease in a woman of fifty years, in which curettage, and packing with iodoform gauze, proved the case to be one of incomplete abortion with retained putrefactive débris. The author believed that if every case of inevitable abortion was submitted to an antiseptic curettage properly done, the mortality would be nil, excepting criminal abortions. He believed that the expectant plan of treatment will produce the best results in the hands of the general practitioner, so long as fever, excessive hemorrhage and putrefaction are absent; any retained débris should be removed, for, even though it does not produce fever or sloughing, it may cause inflammatory disease of the pelvic organs and invalidism. The author referred to a case which he operated upon for bilateral laceration of the cervix and lacerated pelvic floor, no disease of the adnexa, in which the uterus was literally filled with débris, the woman admitting to over 20 self-induced abortions. When abortion is inevitable, the uterus should be at once thoroughly emptied under anesthesia. The treatment of sapremia following abortion should be by emptying the uterus and thorough disinfection of the genital tract with intrauterine douches of formalin 1.1,500; or sublimate solution 1.3,000 or 4,000, followed by normal salt solution, to avoid the danger of mercuric poisoning. The treatment of septicemia depends upon the character of the infection and may be either by measures tending to neutralize the bacteria, or surgical by the evacuation of pus or the removal of the diseased organs. Difficulty of differential diagnosis is experienced when typhoid makes its first appearance at childbirth. Intravenous injections of normal salt solution, quinine, strychnine, digitalis and atropine, as indications arise; and careful regulation of the diet should be enforced, and in severe cases collapse may be overcome by ammonium carbonate per rectum and nitroglycerin hypodermatically. The treatment of septicemia due to streptococci should be by means of antiseptic uterine douches and drainage by loosely packed iodoform gauze; curettage should not be employed owing to its likelihood of spreading the germs and the production of general infection in an already localized case. Pryor advocates the isolation of the infected uterus between masses of iodoform gauze and local and systemic iodism, to destroy the cocci, locally and systemically. Pus tubes and ovarian abscesses should be removed, either per vagina, or by abdominal incision, depending upon the accessibility of the lesion and the condition of the patient.

Etiology and Medical Treatment of Abortion was considered by Dr. I. P. Strittmatter, who stated that the most frequent causes of abortion in his experience had been as follows: (1) Prior criminal abortion; (2) syphilis; (3) pyosalpinx; (4) backward displacement of the uterus. In the first class of cases, careful curettage and packing and general tonic treatment; in the second class of cases, administration of the iodides and general antisyphilitic treatment, and in the fourth class suitable operation had given the best results. In those cases in which there is a relaxed condition of the muscles and joints, with frequent attacks of rheumatism and sometimes attended by heart lesions, antirheumatic treatment should be instituted.

Medicolegal Aspects of Criminal Abortion.—This paper was read by Thomas W. Barlow, Esq., of the Philadelphia Bar, in which he referred to a paper written by Dr. Andrew Nevinger in 1870, who was then President of the Philadelphia County Medical Society, in which he urged upon the clergymen to exercise their influence with the women of the church in reference to the crime of abortion and calling their attention to the consequences of it; and urging the passing of a law prohibiting it. He referred to the difference in the laws of various States on this subject, and called attention to the fact that the law of Pennsylvania applies to an abortion committed at any time during pregnancy, while in other States it must be done when the woman is "quick" with child. He believed that the laws of Pennsylvania were quite sufficient in this respect and that if the crime was increasing it was due to the nonexecution thereof by those on whom the obligation rests. He referred to the function of the police department, detective department, magistrates, coroner, district attorney and courts in the prosecution of such crime, and stated that it was impossible that all should be accomplished by the police power, and suggested that the work against the professional abortionist rests entirely within the medical profession itself. He recommended that a committee be appointed to take charge of the matter, which he believed would have a deterrent effect upon such lawbreakers.

Dr. Richard C. Norris, in the discussion, stated that while he appreciated the sentiment that prompted Mr. Barlow's suggestions, he felt that there were certain practical difficulties in the way, the chief of which was the confidential relation that existed between physician and patient, which deters the physician from reporting the case to the authorities, particularly, as is frequently the case, when a physician is called in after an abortion has been committed one or both of the parties are of high social standing. Another difficulty is the shrewdness with which the abortionists do their work, making it almost impossible to secure legal evidence against them. Many of them even subject their patients to an oath, who in numerous cases, even with a knowledge of impending death will not reveal the author of the crime, owing to the sanctity of the oath. He believes that the appointment of a committee might have a deterrent effect upon a certain class but that the most good could be accomplished by the medical profession by

teaching their patients the moral wrong and great danger of the procedure.

Dr. A. M. Eaton urged that the physician impress upon any patient who should request him to perform an abortion the moral turpitude of the crime, and referred to three cases, in which the women had desired to have act committed, who had been deterred therefrom by his suggestion to go to a secluded part of the city until after the birth of the child. He referred to the case of a barber who stated that he had performed over 250 abortions without any fatalities by taking a soft catheter, inserting it in the womb and injecting milk and carbolic acid "until something gave way."

Dr. Mordecai Price stated that he never treated a case of abortion until he was informed who had performed the operation, which course he deemed necessary for the safety of the attending physician. In any case in which the fetus is dead, he believed that it should be removed at once, and when either the membranes or the fetus are discovered to be coming away, the uterus should at once be emptied, with the hand, the curette being used only in cases of necessity. He did not sanction irrigation of the uterus with any fluid and particularly deprecated bichloride of mercury douche.

Dr. A. C. Morgan referred to a case which had come under his notice in which the girl was of very high standing socially, and in which he felt that his professional relation would have prevented him from giving evidence to convict the abortionist, and this, he agreed with Dr. Norris, was the practical difficulty in the way of the conviction of these men.

Dr. W. E. Parke raised the question as to whether the physician should report a case when he is called in or should the whole thing be kept quiet. He referred to a case which he had seen, in which there had been bleeding and straining for twenty-four hours, and although the patient absolutely denied any action to induce abortion, it was evident that such was going on. No urine had been passed since the beginning of the attack, and catheterization yielded about a dram of almost pure blood, which could not be accounted for. A few hours later the uterus was cleaned out and three hours thereafter catheterization yielded about a dram of a slightly less bloody fluid. The next morning it was discovered that there was an opening from the bladder into the genital tract. The patient apparently improved; the temperature became normal and the pulse nearly so for about two weeks, when she was taken suddenly worse and died. The conclusion was reached that the fistula in the genital tract was produced by pushing something into the bladder through the vagina or cervix, in an attempt to produce an abortion.

Dr. Henry S. Cattell recommended that a black list be kept by a Committee of the County Medical Society of all the physicians and others who are suspected of doing this work, which should only be accessible to such committee, and believed that many physicians would give information to such a committee, with the understanding that it would not be given publicity, that they would not give otherwise. He stated that he made attempts by communicating with the post-office authorities at Washington to have the mail of certain of such practitioners withheld, but had been informed that there was not sufficient evidence to warrant this course.

The papers were also discussed by Dr. Anna M. Reynolds and Dr. Hammond, who, in closing, felt that the untoward effects produced by the use of the curette were rather the fault of the operator than the instrument. He stated that he could see no reason for objecting to free irrigation of the uterus, as any infected wound should be treated by irrigation and drainage; if bichloride of mercury douche is used it should be followed up by normal salt solution in order to prevent mercurial poisoning.

Thomas W. Barlow, Esq., in closing, urged upon the audience their duty to report every case of crime of which they had knowledge, but whether the relations with the patient were such as to deter such action he felt must be decided by the physician in the individual case. He also dwelt upon the importance of the coroner's office and the necessity for the continuance thereof.

BOOK REVIEWS.

Army Inefficiency, its Greatest Cause. By A. C. Profeit, M.B., Lond. J. & A. Churchill, London. P. Blakiston's Son & Co., Philadelphia.

The preface of this little book states that the greatest of all causes of army inefficiency is the excessive prevalence of venereal diseases. It continues: "It is idle to expect efficiency until some steps are taken for their prevention." The author discusses the condition of affairs with regard to venereal disease in the British army in the various parts of the world and the history of the Contagious Diseases Act which was meant to prevent them, did actually accomplish good, but has been repealed. The book is all the more interesting, now that in this country we are in a position in which we are compelled to maintain military forces larger than before, and in various parts of the world.

The American Year-Book of Medicine and Surgery for 1904. Under the editorial charge of George M. Gould, A.M., M.D. In two volumes. Volume I, including *General Medicine*. Octavo, 673 pages, fully illustrated. W. B. Saunders & Co., Philadelphia, New York, London.

It is an axiom that every practitioner of medicine should attempt to keep abreast of the progress of his science. Doubtless the great majority of them realize this fact, some more acutely than others. Yet the activity of research in every branch of the art is so remarkable, and the volume of publication so enormous, that the task becomes a practical impossibility, if it is attempted at first hand. It is to the various compends, "Centralblätter," and so forth, that the practitioner must look for a summary and criticism of what is new, and what claims to be good. Saunders' Series of American Year-Books have long been known as one of the best types of this class of literature, and, under the general editorial supervision of Dr. George M. Gould have achieved an excellent reputation for thoroughness and good judgment. The Year-book of Medicine for 1904 is no exception to the rule set by its predecessors. The subject has been divided into ten sections, which include not only the branches of general medicine, but also pathology, hygiene, chemistry, legal medicine and materia medica. The general plan of summarizing the more important literature of the year, both American and foreign, has been adhered to, and these briefs are in most cases illuminated by critical remarks by the editors. Fair-mindedness and a certain breadth of view are, therefore, essentials in the make-up of a work of such a nature, since the bias of the reader is largely determined by the editor. It is a pleasure to find that these qualities are nowhere lacking in the book, and one may accept the obiter dicta of the editors in most cases as very sane and conservative criticisms. The general make-up of the book in technical respects is excellent, and the index is ample.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 84. NEW YORK, SATURDAY, MAY 28, 1904. NO. 22.

ORIGINAL ARTICLES.

SOME NOTES ON VOCAL FREMITUS.[1]

BY WILLIAM N. BERKELEY, A.B., M.D.,

OF NEW YORK;

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY; ASSISTANT IN MEDICINE, UNIVERSITY-BELLEVUE MEDICAL COLLEGE; ASSISTANT IN PATHOLOGY, PRESBYTERIAN HOSPITAL.

IN the current text-books the notices of palpation of the chest as a means of physical diagnosis are, I think, surprisingly inadequate. And after talking and working with medical men—many of them well-trained and acute observers—who come from various colleges in the United States and Canada to this city for study, one can hardly avoid the impression that palpation has fallen into professional disesteem. Every one seizes his stethoscope and at once begins to listen,—as though in comparison with auscultation all other methods were negligible. When, for example, I say that the first and earliest sign of pneumonic consolidation, antedating bronchial breathing and pectoriloquy by twelve to thirty-six hours, is increase of *fremitus* over the suspected area, I am not infrequently met with confessed ignorance or even with incredulity. I venture therefore to make herewith a modest plea for palpation.

And inasmuch as the palpation of the heart and vessels is a large subject naturally falling into a division by itself, I shall limit myself to-night to some rather irregularly arranged observations on *vocal fremitus.*

The Latin word *fremitus* might be nicely defined by its English equivalent *growling.* The French physician Reynaud *(Journal Hebdomadaire,* 1829) is said to have been the first to observe its practical value in physical diagnosis. Fremitus may be classified as (1) *rhonchal,* arising from coarse râles, moist or dry; (2) *tussive* or *tussile,* from coughing; (3) *borborygmic,* from transmitted gurgling of intestinal gas; (4) *pleuritic,* (5) *succussive,* (6) *cardiac* and *vascular,* and (7) *vocal.*

Vocal fremitus is cognized by the touch and pressure senses. It is the jarring or "growling" sensation imparted to the fingers by vibrations from phonating vocal chords when the hand is placed on certain parts of the patient's body.

The source of the sensation, the vibration of the chords, is reinforced by the resonance of the mouth and nasal passages. The oral resonance is greatest for tactile purposes when the vowel sound of $\bar{o}$ in *soon,* or $\breve{oo}$ in *foot* is made, the mouth cavity then being at its longest by the protrusion of the lips, and the fundamental note of the chords (that of lowest pitch) being reinforced, while the overtones (of less volume and higher pitch) are practically effaced. This curious fact, long ago experimentally brought out by students of the subject and fully confirmed scientifically by Helmholtz, can be verified by any one for himself when an intelligent male patient is in hand with good control of the voice.[1]

Instead, then, of the stock phrases "one-two-three" or "ninety-nine," the patient can often with better advantage be required to *sing* the sound $\bar{oo}$ or $\breve{oo}$ in as bass a voice as practicable, or to speak words like *good, boodle, rood, moon,* and no combination of words should be used in which *h, k, t, p, ph, f, th, ch, sh,* or *s* appears, as their proper pronunciation momentarily suspends the vibration of the chords.

Vocal fremitus is of course more reliable when the patient can maintain the initial pitch and intensity of his utterance to the end of the trial. This is a common source of error with students, the subject dropping his voice from fatigue or inattention when half way through the vocal exercise. In cases of extreme weakness or of aphonia from whatever cause, I have thought that a substitute for the vocal chords might be supplied by a reed horn of good size between the patient's lips, but from other considerations this resource would naturally be of limited usefulness.

I need stop only a moment to observe that the vibrations of the voice whether palpated or listened to, have of course *quality* or *Klangfarbe* as well as *pitch and intensity;* but inasmuch as the quality is nearly invariable in the individual patient, we will consider pitch and intensity only.

The variation of the fremitus with the varying loudness of the voice is familiar to all beginners; the louder the voice the *longer* the individual sound waves are, and a large wave of any length is of course more palpable than a small one; though I am not satisfied that the two vary in mathematical ratio.

As to *pitch,* the lower the *pitch* of the voice, the fewer the vibrations per second; and the fewer the vibrations, the more perceptible to the nerve ends the individual waves again become. The practical value of this fact is, however, overlooked in the text-books. With women and with reasonably intelligent children over six years of age, a marked improvement in the palpability of the fremitus can be obtained at once, if the patient be told to speak in as deep a voice as possible instead of in the usual shrill tone. The fremitus over the lower part of the left lung so often absent—*i.e.,* subliminal—in the patients mentioned, can by this means be usually magnified to a degree readily perceptible to the fingers.

Palpation of the fremitus should be made with

[1] Read before Section in Medicine, New York Academy, January, 904.

[1] A fact observed long ago may be incidentally noted, that when egophony is absent or only feebly present with other vocal sounds, it may be made much more apparent to the ear by phonation of the same sound, $\bar{oo}$.

the hand the observer uses most, and with the palmar surface of the four fingers. Usually not enough vibrations are taken up by two or three fingers to form a reliable judgment. Sometimes only the whole hand can collect a palpable vibration, the motion being otherwise subliminal. I do not think the *side of the palm* is the best means of testing fremitus; first, because its superficial area is often too small; secondly, because the palmar surfaces of the fingers and hand have many more tactile nerve endings to the square inch than the side of the palm has; and thirdly, these nerve endings are usually highly specialized by frequent use. Two symmetrical areas of the chest should be compared *successively* with the same hand; in using two hands at once the hand less often exercised will be less sensitive, and, moreover, the attention is divided and a nice distinction prevented.

An instrument of precision (less cumbersome than the large machines of the physical laboratory) for determining the exact intensity of fremitus is greatly to be desired, and ultimately it will doubtless be invented; but meanwhile a highly trained tactile sense is often capable of extraordinarily fine discriminations, and there seems to be no limit to its perfectibility by practice.

It is usually stated that fremitus is conveyed to the chest through the wind-pipe, aerial vibrations being transmitted on the principle of the speaking tube. This doubtless is true, but it seems reasonably sure that the stout and firm walls of the trachea and bronchi also assist, and perhaps to a marked degree. Fremitus is also conveyed by the vertebral column and true ribs. A brisk fremitus can be felt at the top of the head, on the back bone, and even on the sacrum when a strong male larynx is phonating. The rib fremitus, however, is probably impalpable; at all events being equally conveyed to the two sides it has only a secondary bearing on diagnosis.

I think it ought also to be noted that accumulations of fat and muscle on the exterior of the chest are not so destructive of fremitus as is usually observed. I noticed in a patient recently under observation, who had congenital absence of the right pectoralis major and minor, with absence of the anterior fold of the right axilla and apparently normal lungs,—that the right fremitus seemed very little increased over the right thorax in comparison with the left.

All teachers emphasize more or less the excess of the vocal fremitus on the right side, in front. Some of the text-books give forth a more dubious sound when speaking of the relative fremitus behind. As a matter of fact fremitus is everywhere larger on the right side than over any *symmetrical portion* of the left side; and the posterior right-sided fremitus is often larger than the anterior. That is, I think it safe to say that in 60 to 75 per cent. of cases with the patient in the usual position for examining the back, the right vocal fremitus below the angle of the scapula is *absolutely* larger than over any other part of either right or left chest.

The dextral excess is usually, and I suppose correctly, explained as the result of the relative anatomy of the right and left bronchus, into which it is needless to enter. A. A. Smith affirms, and I think with correctness, that the heavy and firm mass of the liver reenforces and reflects the dextral fremitus.

I wish to remark also on the *degree* of the right-sided excess. And first as to age, excess of right fremitus is physiologically greater from the tenth to the twenty-fifth year than at other ages. This fact was also first called to my attention by Dr. Smith. The reason is doubtless developmental; some satisfactory explanation might be found by measurements of the relative growth of the right and left bronchi during adolescence. None such have been made, so far as I am informed, but patient observation in a large clinic for some years will convince almost any skeptic that the assertion is true.

A numerical comparison of the normal right and left fremitus may seem far-fetched and even provoke a smile when the fingers are the only guide. I venture, however, to affirm that if (with the age limitation just mentioned) the right subclavicular fremitus be called 3*a* the left will be usually 2*a;* or, if the right be 4*a* the left will be 3*a,* making a normal ratio (right to left) of 3 : 2, or 4 : 3. When the right excess becomes greater than this and the ratio becomes 3 : 1½ or 4 : 2, or 6 : 3, the condition is *pathological,* though from fremitus only it is not always possible to say what is wrong.

Another important fact (perhaps already observed and described by some one, though I have found no printed reference to it) is that the palpable vibration gotten by putting the four fingers transversely and snugly over the larynx (Adam's apple) is generally four or five times as great as the right subclavicular fremitus; the two being related as 5 : 1 or 4 : 1. *If the right or left subclavicular fremitus becomes for any given voice widely variant from this ratio, the condition is pathological.* I find that a diagnosis of consolidation of the right apex when the laryngeal fremitus is to the right subclavian fremitus as 4 : 2 or 6 : 3, is usually confirmed by the other signs. If this seems an *ex cathedra* statement, I ask only that it be given a careful trial before it be disputed.

The normal relation being as described, when the fremitus on the two sides is *equal* we confront a difficulty, namely, Can it be an accidental anomaly, or is it pathological? Here, of course, the autopsy would be the ultimate appeal, but if we may draw safe conclusions clinically, I should say that the right-sided excess is one of the most fixed and permanent phenomena in thoracic diagnosis, and that in 99 cases out of every hundred bilateral equality is pathological. *A fortiori* sinistral excess is pathological.

The causes of equality or of left-sided excess are in general four:[1] (1) Left consolidation;

[1] Mutatis mutandis the first three also explain pathological right-sided excess.

(2) Any process on the right side which dissociates the visceral from the costal pleura; (3) Obstruction of the right bronchus; (4) Transposition of the viscera.

These points might be elaborated, but my time is short. I may say as to obstruction of the right bronchus, however, that it may be the most baffling of all the causes. Plugs of mucus, mucous polypi, bronchial stenoses, foreign bodies, diphtheria membranes, the pressure from without of aneurisms and lymph-nodes and mediastinal tumors—must at all times be considered. When the first three causes can be reasonably excluded and the heart cannot be found on the left side, transposition is a justifiable and highly probable diagnosis.

A conventional statement in the text-books requires brief notice here, namely, that vocal fremitus is less than normal in vesicular emphysema. Some years' personal study of emphysematous chests will convince the unprejudiced observer that it is not true. Simple dilation of the air-sacs with partial atrophy of their walls does not modify palpable fremitus to any serious degree either way. Of course these patients usually have a hoarseness due to chronic laryngitis, and this, it may be claimed, increases the quantity of vibration at its source. But comparison of the laryngeal and subclavicular fremitus in the way I have suggested will show normal relations.

An odd fact, so rarely noticed as to be a mere curiosity, is, that in old women and small anemic children with flabby tissues and soft trachea, the relation of right to left side may be changed by holding the patient's chin high and rotating the head to the left. This perhaps artificially compresses the right bronchus by traction and torsion of the windpipe.

A single additional note may be made in conclusion. Fremitus with a sitting or standing patient will be increased slightly if he lies down on a hard bed or table; lying on a soft bed makes no difference that after many trials I could ever notice with the unaided fingers.

40 East Fifty-eighth Street.

RESULTS IN DIFFUSE SEPTIC PERITONITIS TREATED BY THE ELEVATED HEAD AND TRUNK POSITION.

BY RUSSELL S. FOWLER, M.D.,

OF BROOKLYN, N. Y.;

SURGEON TO THE GERMAN HOSPITAL; ADJUNCT SURGEON, BROOKLYN HOSPITAL; ASSISTANT SURGEON, M. E. (SENEY) HOSPITAL.

FROM October 17, 1899, to January 17, 1904, Dr. George R. Fowler and myself have operated upon one hundred well-marked cases of diffuse septic peritonitis, resulting from inflammation of the vermiform appendix. We have not refused operation to any case, however desperate. Of these cases, 67 per cent. have resulted in recovery. The certainty with which the vast majority of cases of diffuse septic peritonitis, however treated, died in the past, is well known. Any method of treatment which will lower the tremendous mortality is worthy of consideration. It is with the purpose of bringing such a method to your attention that this paper is presented.

The technic employed in the treatment of these cases is as follows: The abdomen is entered through an incision not larger than is absolutely necessary to deal quickly with the primary focus of infection. All accessible infection is sponged away with stick sponges wrung out of a 1-3,000 bichloride solution. The primary focus of infection is isolated with laparotomy sponges wrung out of bichloride solution and removed. The immediate neighborhood is flushed with a solution made up of equal parts of peroxide of hydrogen and a saturated aqueous solution of bicarbonate of soda. This solution may be used slightly warm. The foaming peroxide-soda solution is washed away with saline solution at a temperature of 110° F. The neighborhood is then dried. Accessory collections of pus in the pelvis, under the liver and between coils of intestine are searched for, opened up, and irrigated in a similar manner. Finally a Chamberlain douche tube is placed in the pelvis and then in other parts of the abdominal cavity, and peroxide-soda solution introduced through it. The entire abdomen and pelvis is then flooded with hot saline, the Chamberlain douche nozzle being moved from one point to another. The intestines are at no time allowed to escape through the wound. The escape of the solution is facilitated by introducing the fingers into the wound.

The tubing conveying the saline should be of large caliber to allow of rapid flushing. The flushing with saline continues while the wound is being sutured. A large curved-glass drainage tube is introduced into the pelvis, its upper end emerging from the lower angle of the wound. There are numerous small fenestrations in the end of the tube. No other drainage is used unless there are necrotic abscess cavities in which case a wicking drain is placed therein and emerges alongside the glass tube. Finally the douche nozzle is withdrawn and the sutures tied. Eighty cases were so treated. In females drainage has in some cases been through a posterior colpotomy done from within the abdomen. In five personal cases I have relied upon this alone, closing the abdominal wound without drainage. In such cases the drainage tube is of very large caliber, of rubber, and through it are led numerous strands of wicking. This latter would seem to be the ideal way of treating such cases in females. In 22 cases, in place of a large glass tube in the pelvis, from 12 to 21 bundles of wicking or gauze strips have been led from various parts of the pelvis and abdomen to emerge from the lower angle of the wound.

The glass drainage tube is dressed independently of the wound. This is done by nicking a 12-inch square of rubber dam in the center, putting the rubber on the stretch and pressing the neck of the tube through the opening thus made. A narrow strip of gauze is passed to the bottom of the tube to act as a capillary drain. The upper

end of the strip is placed in the center of a yard of loosely rolled gauze. The edges of the rubber dam are caught up and tied so as to form a bag in which the gauze is enclosed. The wound is dressed with plain gauze held in place by adhesive plaster. The binder is split to allow the tube dressing to emerge. Thus pressure upon the tube is avoided and the tube can readily be aspirated and a fresh dressing applied.

Directly after operation the patient is placed in the elevated head and trunk position. This may be done by placing a chair or stool beneath the head-piece of the bed. At the German Hospital, we employ a frame consisting of two side supports and a central bar connecting the two. The side supports have each three holes at different levels into which the connecting bar may be introduced according to the height desired. This frame is secure and allows of different levels being employed. The elevation should never be less than one foot. A folded pillow is placed against the buttocks and through the fold of the pillow is passed a stout bandage which is tied on each side to the head of the bed. This allows the patient to rest comfortably and maintains his position without exertion on his part. Moreover, the knees being flexed relaxes the abdominal wall and this is always grateful to the patient. A saline enema is given every three or four hours for four to six times. If gas does not pass freely, a high enema of turpentine and oxgall is given. Strychnine and whisky are administered hypodermatically to combat shock. Fluids by the mouth are given ad libitum. The glass drainage tube is redressed every four hours and its contents evacuated. After three or four days, when the discharge is lessening, a smaller rubber tube is introduced through the glass tube and the glass tube withdrawn, leaving the rubber tube in its place. This is shortened from day to day and finally replaced by a strip of plain gauze.

Before our employment of the elevated head and trunk position in the after-treatment, we saved about 25 per cent. of this class of cases. For the reason that satistics of a few cases may be misleading, beyond a preliminary report of 13 consecutive cases of diffuse septic peritonitis with but one death,[1] we have reported no further results until the present, preferring to wait until we could show results in a sufficiently large number of cases to give a fairly true idea of the merits of the treatment. At the German Hospital we have operated upon 46 consecutive cases with but nine deaths, 81¼ per cent. of recoveries; at the M. E. (Seney) Hospital, 30 cases with 12 deaths, 60 per cent. of recoveries; at the Brooklyn Hospital 22 cases with 12 deaths, 45½ per cent. of recoveries.

Practically the only way in which treatment differed was in the drainage. Eighty cases were drained by placing a large glass tube in the pelvis. In some there was used supplemental gauze or wicking drainage for necrotic areas. Thirty of these cases died. One case was drained by a glass tube in the pelvis and a rubber tube through the posterior vaginal fornix. This case recovered. Five cases were drained per vaginam. Of these one died. Twelve cases were drained with multiple bundles of wicking or gauze strips. Two of these cases died. One case was drained through a rubber tube in the lumbar region, and recovered. One case was closed tight without drainage, and also recovered.

Of the 33 deaths, 17 occurred within twenty-four hours after the operation. These cases were profoundly septic and nothing could have saved them. On the second day, five cases died of profound sepsis, one of meningitis, one of lobar pneumonia. On the third day, four cases died of profund sepsis. On the fifth day one case died of septic pneumonia. On the eighth day one case died of septic ulceration of the stomach and general sepsis. On the thirteenth day one case died of meningitis and one of septic pneumonia and right-sided empyema. On the thirty-second day one died of septic endocarditis.

All the cases operated upon with one exception, even those which lived less than twenty-four hours, showed an immediate and decided improvement of the peritoneal condition. Vomiting was allayed, gas passed freely, distention diminished and they became more comfortable. The one exception was a case drained per vaginam who died on the second day of profound sepsis without any abatement of the peritoneal symptoms.

I would state the salient points in the treatment of these cases as follows: (1) A small incision and the avoidance of eventration; (2) thorough cleansing of the primary focus of infection and removal of the appendix. (3) Evacuation and cleansing of all accessory abscess cavities and the pelvis before washing out the peritoneal cavity. (4) A rapid systematic flushing of the peritoneal cavity with peroxide-soda solution followed by hot saline. (5) The continuance of the saline flushing until the sutures are placed, and for the most part tied. (6) The provision of proper drainage for the pelvis either by means of a large glass tube containing a capillary drainage strip emerging through the lower angle of the wound or, in females, by a large caliber rubber tube filled with wicking passed through a posterior colpotomy incision. (7) The drainage of accessory abscess cavities with gauze or wicking. (8) The elevation of the head of the bed to accelerate the drainage of septic fiuid into the pelvis where it can be removed through the glass tube or, in case of vaginal drainage, find a ready exit.

[1] These cases were reported in the *Medical Record* for April 14, 1900, and January 16, 1900. With two exceptions the peritonitis followed appendicitis. The two exceptions were due, one to a ruptured ovarian cystoma with a twisted pedicle, the other followed an operation for ventral hernia and was probably due to infection in a heavy strand of catgut. The fatal case developed meningitis on the eleventh day following the operation, and died on the thirteenth day. The peritoneal symptoms had subsided.

Philadelphia Hospital Examination.—At the recent examination of candidates for resident physicians, 41 of the 85 applicants made the required average of 70 per cent. Of the 19 highest on the list who will be appointed to fill regular vacancies, University of Pennsylvania has 16, Jefferson 2, and Medico-Chirurgical 1.

TWO APPLIANCES TO FACILITATE EYE AND THROAT WORK.

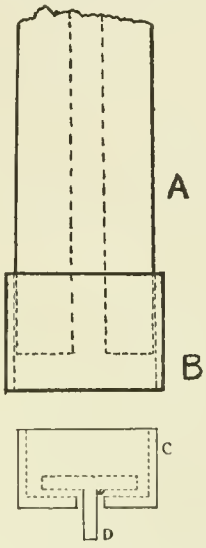
BY EDWARD B. COBURN, A.M., M.D.,
OF NEW YORK;
ASSISTANT SURGEON AND PATHOLOGIST TO THE NEW AMSTERDAM EYE AND EAR HOSPITAL.

Any device which aids in medical practice must depend for success upon its paramount utility. So, the two appliances, herewith depicted will have their fate decided by their ability (or lack of it) to fill a long felt want.

The first appliance is a shield to prevent disagreeable and annoying reflections from the posterior surface of trial lenses used by oculists to determine refraction. For many years I have been bothered by patients complaining that the glasses were "dim," looked "smoky," or objects behind or at the side were seen by reflection in the glasses. Most oculists have their patients sit near a window and the reflection of the window-sash, curtains, or objects out-of-doors is quite sufficient to distract the patient's attention and so prevent a proper fitting of the glasses, besides taking time and trying the temper of the physician by the uncertain answers. Usually it has been sufficient to have the patient hold the hand or a card at the side of the head corresponding to the eye which is being tested, but this becomes tiresome during a long examination, and is even impossible to stout persons. Finally, the difficulty was solved by having a pair of shields made connected by a curved steel spring long enough to go over the patient's head and adjusted so as to clasp the head firmly without undue pressure. The wings or shells are made of aluminum, blackened and measure 4 by 6 inches. The part of the shield which comes in contact with the head is padded so that no discomfort is caused. The pads usually rest on the temporal region just above the zygomatic process in front of the ear.

The shield is made in three parts, the wings being attached to the spring by thumb screws and one or both wings may be used at a time. Of course it would be impossible to use this device on women wearing hats, but as it is quite impossible to examine the eyes with the present style of wide-brimmed hats, their removal before the examination becomes necessary and no obstacle is offered to its use. The shield (Fig. 1) was made for me by Gall and Lembke and might be called an oculist's reflex shield.

In using sprays to treat diseases of the larynx or nasopharynx an appreciable length of time elapses between the opening of the air valve by the thumb of the operator and the actual issuance of the fluid from the tip of the instrument. This is particularly the case where aspiration is the principle employed; *i.e.*, a stream of air passing over the mouth of a tube exhausts the air from it, creating a partial vacuum, and fluid from the receptacle into which the tube is placed is forced upward by atmospheric pressure. The larger and longer the tube the longer interval before the fluid emerges, and the weaker the air pressure used to



exhaust the tube. Where the air pressure is applied directly to the surface of the fluid in an air-tight receptacle the interval is not so great, but is still appreciable. The column of cold air (especially in the former instrument) with perhaps a few drops of fluid causes the patient to gag. When the larynx is closed or the soft palate is retracted against the posterior wall of the pharynx, an effective cleansing or medication of the parts becomes impossible. The spray may be made practically instantaneous and the parts treated before the spasm occurs by having the tube already filled with the desired fluid. This may be accomplished by placing a valve at the lower end of the tube which rests in the fluid and so preventing that in the tube from returning to the general body of fluid in the receptacle.

A sleeve (B) is made which is fastened to the spray-tube (A) by wax or other material, and the valve seat (C) is provided with a high rim or collar which fits snugly over the part B, the latter being slightly beveled from above downward.

The Valve D is ground accurately to the valve seat and is provided with a stem, triangular in cross-section, which passes through a circular opening in the valve-seat, thereby permitting the fluid to flow freely upward during use. The valve is made sufficiently small to permit fluid to pass around it into the tube above and raises slightly during use, but when the air pressure is removed the valve drops back into its seat and the fluid is retained in the tube.

This attachment may be made of brass or bronze (silver or gold-plated to prevent attack by the medicaments used), glass or aluminum. The latter answers well for general purposes. Only slightly greater air-pressure is required to operate the spray tube with the valve attached than without it.

It may be objected that this device is unnecessary as in spraying the post-nasal space a palate-retractor may be employed, but its use is unpleasant without cocaine and the latter is also unpleasant, if not dangerous.

I am indebted to Mr. John T. Hoyt, of the Physiological Laboratory, College of Physicians and Surgeons, for his kindness in making this attachment.

63 West Fifty-sixth Street.

A STUDY OF THE TUBERCULOSIS PROBLEM IN NEW YORK CITY.[1]

BY JAMES ALEXANDER MILLER, A.M., M.D.,

OF NEW YORK;

ADJUNCT ASSISTANT ATTENDING PHYSICIAN AND PHYSICIAN TO OUT-PATIENTS, BELLEVUE HOSPITAL; ATTENDING PHYSICIAN TO SETON HOSPITAL AND HOUSE OF THE HOLY COMFORTER.

It is impossible to discuss all the many phases of this subject within the limits of any one paper. The object of this present study is to deal with those aspects of the tuberculosis problem which are of practical interest and importance to the physician, as he actually meets with tuberculous patients in private or dispensary practice among the poor of New York City—meaning by that, only the Boroughs of Manhattan and Bronx.

Among physicians there are two distinct, and almost diametrically opposite, points of view in regard to this disease when it occurs among the poor. The first is that of the comparatively few men who are interested and actively engaged in the study and treatment of this disease under such conditions; and we find them optimistic, even enthusiastic in regard to it. The other viewpoint is that of the indifferent, or pessimistic, and is, I am forced to believe, that of the majority of the members of our profession.

It is enthusiasm arraigned against indifference. Both will probably need modification before the true position is reached. The cooling of enthusiasm, however, is an easy process; but the warming up of indifference is a more difficult task. It is, nevertheless, for this latter end that we are interested in this present discussion.

Upon the surface, it seems strange that there should be any such indifference, but, on closer inspection, I think that we can trace its origin to the medical school, where we are interested because of the variety of physical signs presented by this disease, but where this interest is checked, by the impossibility of following the results of any continued form of treatment; through the hospital, where our consumptives are recognized only to make sure of a rigorous exclusion, and so any study of this disease is impossible; to the dispensary, where we are immediately overwhelmed by the numbers of these patients, who look to us to help and to cure them.

These patients often live in dark, dirty overcrowded rooms; their food is poor, insufficient and badly cooked; and in order to live, even in this fashion, they must, as a rule, do hard and confining work. These are discouraging conditions under which to apply our modern notions of the treatment of tuberculosis, depending, as it does, upon plenty of light, good air, nourishing food and rest. It is therefore not so surprising that few or no attempts are made so to apply them, and consequently these patients almost invariably do badly and are looked upon as sad, chronic, hopeless cases.

This is the tuberculosis problem in the practical form that it presents itself almost daily to each one of us. It is our present object to throw some light upon this problem, and perhaps to offer some encouragement for the hope of its ultimate solution.

Such a result can perhaps best be accomplished (1) by a brief description of the existing institutions and agencies which have an influence upon this subject; (2) by a demonstration of the way in which physicians may utilize these institutions to meet indications arising in various classes of cases; and (3) by an indication of the extent of our responsibilities toward these patients.

For convenience, these different institutions may be divided according to their functions into: (1) those for education and prevention; and (2) those for treatment.

INSTITUTIONS FOR EDUCATION AND PREVENTION.

The *Health Department* of the city deserves first mention here, both on account of the importance of its work and because of its priority in this field, in point of time. Just ten years ago, the first resolutions were adopted, involving the reporting to the department of certain classes of cases of tuberculosis. This resulted in increased opportunities for inspection and observation, as well as for the distribution of information concerning this disease, by means of oral and printed instructions and advice. The number of cases thus reported increased very rapidly, and the campaign of education grew more extended in proportion, until in 1897 an amendment to the Sanitary Code was adopted, declaring "pulmonary tuberculosis to be an infectious and communicable disease, dangerous to the public health," and making it compulsory for every physician to report all such cases, in the manner now well known and generally observed.

Although this was only seven years ago, it is difficult for us now to realize the general storm of disapprobation which this ruling aroused, even from many of the leading physicians of the city. But, in the light of our present knowledge, I think that it is no exaggeration to say that, directly or indirectly, no single influence has been so potent in bringing home to the community—physicians and laity alike—the nature of this disease, and the means by which its ravages may be success-

[1] Read before the Quiz Medical Society, February 13, 1904.

fully resisted. The scientific soundness of this section of the Code is now universally admitted and it stands to-day unchanged, excepting that all forms of tuberculosis, as well as the pulmonary forms, are now included. The growth of this work is shown by the increase in number of cases reported from 4,166 in 1894, to 13,383 in 1902.

In addition to the educational features of this work already mentioned, there are the visits of the inspectors, who report the conditions prevailing in the homes, as regards light, ventilation, cleanliness, overcrowding, general sanitation, and precautions taken to prevent the spread of infection, etc. They instruct the patient and his family, both verbally and by circulars, in the danger and manner of infection and in the proper disposal of the sputum, and sputum cups are provided for those who cannot afford to procure them for themselves. More recently, trained nurses have been ultilized with great success in this work, especially for the care and observation of the more advanced cases.

Considerable educational value is also attached to the free examination of sputum made by the Health Department, in the emphasis thus placed upon the value as well as the limitations, of this form of investigation. In 1903, over 11,000 specimens of sputum were thus examined.

All of these educational means, of course, make also for the prevention of this disease; but, in addition, must be mentioned the prohibition of spitting in public places and conveyances, the disinfection of rooms after death or removal, and the compulsory removal of those who, either wilfully or for other reason, neglect the proper care of their sputum and consequently are a serious menace to the health of their associates.

The department points with justifiable pride to the results of the foregoing methods of procedure, as shown by the reduction of mortality from tuberculosis. In 1881 the death rate from this disease was 4.2 per 1,000. In 1902 it was 2.29 per 1,000, a reduction of over 40 per cent. Of actual deaths from consumption there were 5,312 in 1881, and only 4,893 in 1902,—418 less deaths, although the population had increased over 700,000.

Such, very briefly, has been the noble work of the Health Department, and it is no more than simple justice to add that it represents practically the efforts of a single man, Dr. Hermann M. Biggs.

The Charity Organization Society must next be considered in its relation to this subject. In June, 1902, its Committee on the Prevention of Tuberculosis held its first meeting, and the following September began its active work. This work is best described by quotations from the statement by this Committee of its own objects.

1. "Research into the social, as distinct from the medical aspects of tuberculosis, for example, into the relations between the disease and overcrowding, infected tenements and unhealthy occupations, and also into the influence upon recovery of improved diet and hygienic living."

During the past year the results of this part of the committee's work are shown in a very comprehensive article by Miss Lillian Brandt, on the "Social Aspects of Tuberculosis," and another by Homer Folks, late Commissioner of Charities, based upon the social history of 1,000 cases in the Phthisis Infirmary of the Metropolitan Hospital.

2. "Education. The publication of leaflets and pamphlets, the giving of lectures, and the promulgation in every possible way of the fact that tuberculosis is a communicable and preventable disease; the widest distribution of the results of scientific research in this field and of the results of modern treatment, both in sanatoria and at home."

This part of the work has been well done. Last winter 81 lectures were given by physicians in various schools, clubs, churches, settlements, etc., in five or six different languages, with an aggregate attendance of 8,700. Other more scientific lectures were delivered at the United Charities Building, and copies of these lectures, with much other educational literature of a popular nature, have been widely distributed.

3. "The encouragement of movements for suitable public and private sanatoria, both for advanced and for incipient cases; for adults and for children; for free care, and also for the care of those who can pay moderate fees."

Under this category comes the activity of this committee in attempts to influence legislation:—twice successful in the recommendations for the establishment of a State Sanatorium and a Municipal Sanatorium, respectively, and once unsuccessful in the efforts to prevent the passage of the Goodsell-Bedell law, which is considered to be almost prohibitory of the establishment of any sanatoria for tuberculosis in this State.

4. "The relief of indigent consumptives by the provision of suitable food and medicine; by the payment of rent, when this is necessary to secure adequate light and air; and by transportation and maintenance at a distance, when, in the judgment of the committee, this is essential."

A good deal of attention has been paid to this feature of the work. For five months all applicants to the Charity Organization Society, where the necessity for relief was caused by tuberculosis in the family, were referred to the Central Committee and, where investigation proved its desirability, relief was given in the form of rent, fuel, special diet, medicine, etc. Provision was thus made for 211 families, and the expense incurred was $1,000 a month. In April, lack of funds, as well as convenience of administration, made it necessary to turn this work back into the hands of the committees of the various districts, and the work of relief is still being carried on by them; but lack of funds curtails its efficiency to a certain extent. The interest taken by the Charity Organization Society in these cases is, however, very great, and this society and its committees constitutes, at the present time, one of the most efficient and potent forces now at work in this city toward the solution of the tuberculosis problem.

The *United Hebrew Charities* has also approached this problem in a most practical and efficient way. It likewise has its special Committee on Tuberculosis, which began its work in January, 1902, several months before that of the Charity Organization Society, and its objects and methods are best described by quotations from its own report:

"The methods made use of by the committee may be classified under the following general headings: (*a*) The placing of applicants in charge of a special agent. (*b*) Careful medical examination to secure a correct diagnosis. (*c*) Instruction of consumptives by means of pamphlets, tracts, etc., and, in particular, by verbal guidance, with special reference to the disposal of sputum, cleanliness of person and home, proper diet and exercise, cessation of unhealthy occupation, removal to more sanitary neighborhood, and, in general, following out the recommendations of the Board of Health. (*d*) Securing the most desirable medical treatment; where possible, in sanatoria. (*e*) Supplying necessary food, such as eggs, meat, etc., in sufficient quantities, and, in particular, an abundant supply of good milk. (*f*) Where change of climate was indicated by the medical examination, granting transportation to points desired. (*g*) Securing, particularly for the improved consumptive, out-door work and, where possible, positions in country towns. (*h*) Friendly visiting."

The general similarity between this work and that of the Charity Organization Society is apparent but considerable advantage is gained by the United Hebrew Charities in the fact that the administration of it is in more compact form and that it has more adequate means at its disposal. Less attention is paid to a general campaign of education and more is done for the individual patient. In fact, it is open to question whether some of this work does not belong more properly to medical jurisdiction; but, if so, criticism should be made rather of us who have neglected it, than of the institution which has taken it up.

The comparatively small number of consumptive Hebrews, the relatively adequate supply of funds, and the close association with the Bedford Sanatorium and the National Jewish Hospital, of Denver, are factors which combine to make this work of the United Hebrew Charities remarkably efficient, and one is compelled to admire the enthusiasm and thoroughness with which this, as well as most other Hebrew charities, are conducted.

Similar to the work of the Charity Organization Society and the United Hebrew Charities, but confined to the assistance of the patients and their families in their homes, is the work of the *Association for Improving the Condition of the Poor.*

This association investigates and relieves the necessities of all suitable cases that are referred to it. This relief includes the payment of rent, the provision of food, coal, etc., and for tuberculosis patients the supply of extra diet, in the form of milk and eggs in abundance. There are at present 300 families under the care of this association, in which the cause of dependence is tuberculosis. The assistance thus given is of the greatest value, and the manner in which this work is carried on is most efficient.

The New York Diet Kitchen Association has seven kitchens or depots, in various parts of the tenement districts. From these kitchens are distributed milk and other forms of simple diet among the sick poor, upon requisition of the physicians of certain dispensaries. Although somewhat in need of funds, they are able to supply milk to many tuberculous patients, and stand ready to help as many more as their means will allow.

The Nathan Straus Milk Depots are also available for a certain number of these patients, although primarily intended for the use of infants and children. These depots are situated in convenient parts of the city, and tickets for milk may be obtained by application to Mr. Straus.

There are numerous other smaller relief agencies in New York, the greater number of which are connected with the various churches. Important among these may be mentioned the St. Vincent de Paul Society, St. Bartholomew's and St. Thomas' churches. Special diet and other assistance may be obtained from them, but it is usually better and more satisfactory to make application for such through the medium of the Charity Organization Society.

Another most important factor in the tuberculosis problem is the *Reform of the Tenements.* The beginnings of the present movement were in 1900, when the New York State Tenement House Commission was appointed, largely through the activity of the Charity Organization Society. This commission studied the whole tenement question thoroughly in every detail, and subsequently practically all of its recommendations were adopted by the legislature and became laws in 1901.

As one result of the new laws, the Tenement House Department was instituted as a separate part of our municipal government on January 1, 1902. Robert W. DeForest and Lawrence Veiller, who had been President and Secretary of the Commission, were appointed Commissioner and First Deputy Commissioner, respectively, of this new department, so that the execution of the laws was placed in the hands of those who had framed them.

The importance of this subject to our present discussion is well recognized, and is apparent from the fact that the great mass of the 20,000, and more, tuberculous persons in this city live in the tenements, and that it is in these tenements that the conditions which we now believe to be most essential for the prevention and cure of tuberculosis—namely, light, air and cleanliness—have previously been unknown and impossible.

The evils of the tenements have thus been summed up in the report of the commission: "Insufficiency of light and air, due to narrow

courts or air-shafts; undue height and the occupation by the building or by the adjacent buildings of too great proportion of the lot area; danger from fire; lack of separate water closets and washing facilities; overcrowding; foul cellars and courts; and other like evils, which may be classed as bad housekeeping."

The present law attacks these evils in three ways:

1. *By the New Tenements.* These must be so built that there is light and ventilation for every room. The air shaft is abolished and the size of courts increased. The height of buildings and proportion of lot space to be occupied are diminished. The halls have windows opening upon large courts, and each family has its own water-closet within its own apartment.

2. *By Altering the Old Tenements.* The main evils here were the dark interior rooms, the dark halls and the common privies, or "school sinks" in the yards. Investigation showed that there were 350,000 dark interior rooms with no windows, in New York. These must now be fitted with large interior windows in the partitions separating them from the outer rooms, thus providing considerable light and air. "School sinks" have been abolished and closets placed upon each floor. The halls must be light enough for an ordinary person to read in any portion of them, and this may be accomplished by windows to the outer air or glass panels in the doors leading to the rooms.

3. *By Adequate Supervision.* This is obtained by careful and constant inspection, to secure the enforcement of the laws. By the combination, in a separate department, of the duties which had previously been divided between the Health, Building, Fire and Police Departments, this supervision has been made possible and practicable, and it is now being consistently exercised.

Attention must also be called to the recommendations of the Tenement Commission in regard to the establishment of small parks in crowded tenement districts to replace unsanitary houses, and to the institution of public baths, playgrounds and recreation piers. A beginning has already been made in these directions, and each one of these improvements has a direct bearing upon our present subject.

Dr. Hermann Biggs thus comments upon the relation of the tenement house to tuberculosis: "There has been a reduction in the mortality from the tuberculous diseases in New York City since 1886 of 35 per cent., and I have no hesitation in saying that I believe, with a complete and efficient scheme for dealing with pulmonary tuberculosis, in the housing of the tenement house population, suitable hospital accommodations and the proper enforcement of precautionary measures, the death rate from the tuberculous diseases in New York City may be further reduced one-third within a period of five years. This would mean a saving of 3,000 lives annually. No other measures offer promise of such large returns in the diminution of suffering and death as those which look to the prevention of tuberculosis in the tenement houses."

Because of the great amount of comment and criticism caused by the action of the Marine Hospital authorities, in classifying tuberculosis as a "dangerous, contagious disease," and therefore excludable under the immigration laws of this country, it may be of interest to note the actual results of this ruling.

From July 1, 1901, to December 31, 1903, a period of two and one-half years, during which this law has been presumably operative, 27 aliens have been certified at Ellis Island as suffering from pulmonary tuberculosis, and of these 19 were deported. As the total immigration at the port of New York during that same time was 1,421,853, it is evident that this exclusion has had no appreciable effect upon our tuberculosis problem.

This completes our review of the more important agencies active in education and the prevention of tuberculosis in New York. We will next consider

THE INSTITUTIONS FOR TREATMENT.

Of these institutions there are three classes: (1) Sanatoria; (2) Hospitals; (3) Dispensaries. The sanatoria and hospitals we will review in bare outline. The dispensaries we will consider more carefully, as having a more immediate bearing upon our especial topic.

Sanatoria.—1. The Adirondack Cottage Sanitarium, sometimes known as the Trudeau Sanatorium, situated at Saranac Lake, N. Y. Capacity, 100. Early cases only. Charges $5 a week. Admission through examination. Examining physicians in New York City: Drs. James, Janeway, Loomis, Trudeau, Jr., and Miller.

2. The Loomis Sanatorium, Liberty, N. Y. Capacity, 135. Main building, 100. $10 to $25 a week. Any cases not bedridden. Admission by application to Resident Physician. Charitable Annex, 35; $5 a week. Early cases. Admission through examination by Dr. Loomis.

3. The Montefiore Country Sanatorium, Bedford Station, Westchester County, N. Y. Capacity, 160. Early cases. Free. Application and examination at Montefiore Home from 11 A.M. to 1 P.M. daily.

4. Stony Wold Sanatorium, Lake Kushaqua, Adirondacks, N. Y. Capacity, 60. Early cases, in working women and children, including boys up to twelve years of age. Free. Application to Mrs. James E. Newcomb, and examination by any member of Medical Board.

5. The Sanatorium Gabriels, Paul Smith's Station, Adirondacks, N. Y. Capacity, 100. Early cases. $10 to $18 a week. One case in every ten, free. Application to Sister Superior, accompanied by any physician's certificate.

6. The National Jewish Hospital for Consumptives, Denver, Colo. (This is mentioned because 50 per cent. of its patients come from this city.) Capacity, 85. Free. Early cases only. Application and examination at United Hebrew Chari-

ties Building on second and fourth Mondays of each month, at 10 A.M.

The total sanatorium capacity is thus 640. Of course only a portion of this number (perhaps one-half) represents the available accommodation for New York City. It will be noted that for the poor there is accommodation only for early cases. All of these sanatoria have a long waiting list and it is useless to make application for patients in even moderately advanced stages of tuberculosis.

Hospitals.—1. Tuberculosis Infirmary of Metropolitan Hospital, Blackwell's Island. Under Department of Charities. Opened February 1, 1902, through activity of Commissioner Homer Folks. Capacity, 450. 350 in buildings and 100 in tent cottages, which are a great feature of the institution. Admits all stages of disease. Admission by physician's recommendation to Superintendent of Out-door Poor, foot of East Twenty-sixth Street. Boat leaves 10 A.M. and 3.30 P.M.

2. Seton Hospital, Spuyten Duyvil, N. Y. Under Sisters of Charity. Capacity, main hospital, 200—men only. Annex called House of Nazareth, for women and children, accommodates 180, making total capacity of 380. Admits all stages of disease. Admission through Superintendent of Out-door Poor, and city pays for board of each patient thus admitted.

3. St. Joseph's Hospital, East One Hundred and Forty-third Street and St. Anne's Avenue. Under Sisters of St. Francis. Capacity, 350, with 15 beds for children. All stages of disease. Application with physician's certificate at the hospital at any time, or through Superintendent of Out-door Poor.

4. Riverside Hospital. North Brothers' Island, under Department of Health. Capacity, 60. Admits all stages. Application through Health Department, who will compulsorily remove any case considered dangerously infectious.

5. House of Rest for Consumptives, Inwood-on-Hudson. Capacity, 35. Designed as a refuge for incurable cases. Admission by application to the Attending Physician, Dr. Linsly R. Williams. (This is the organization that for about ten years had its patients in St. Luke's Hospital.)

6. Lincoln Hospital, East One Hundred and Forty-first Street and southern Boulevard. Has two phthisis wards. Capacity, 40 beds. Admits all stages. Application at hospital or through Superintendent Out-door Poor.

7. Montefiore Home, Broadway and One Hundred and Thirty-eighth Street. Has phthisis wards accommodating 45. For advanced cases. Application at the Home between 11 A.M. and 1 P.M.

8. Bellevue Hospital. Has two phthisis wards accommodating 40 patients. They are for cases developing in the regular wards, and others who are too sick to be transferred to Blackwell's Island.

9. In Brooklyn. The Brooklyn Home for Consumptives and the Kings County Hospital receive tuberculosis patients, but with them we are not now immediately concerned.

All of these hospitals are entirely free. The male wards are overcrowded during the winter, but there is always room for women.

The Seton, Riverside and Metropolitan hospitals are fairly well adapted for the treatment of early cases. The others are better fitted to care for advanced and more or less hopeless cases. The Seton Annex, or House of Nazareth, is an excellent place for children.

The total hospital accommodation is 1,400.

Summary of Beds.—

SANATORIA.		
Montefiore, at Bedford	160	
Loomis	135	
Adirondack Cottage	100	
Gabriels	100	
National Jewish Hospital	85	
Stony Wold	60	640
HOSPITALS.		
Metropolitan	450	
Seton	380	
St. Joseph's	350	
Riverside	60	
Montefiore Home	45	
Lincoln	40	
Bellevue	40	
House of Rest	35	1,400
Grand total		2,040

There are prospects in the near future of an increase in these accommodations in the following ways: (1) by the opening of the State Hospital at Ray Brook, Adirondacks, N. Y., which is nearing completion; (2) by the erection of a Municipal Sanatorium, upon which favorable action has already been taken by the city authorities, but the selection of a suitable site is hindered by the provision of the Goodsell-Bedell law to which allusion has already been made. (3) The Free Masons have a plan on foot to erect a sanatorium for the tuberculous members of their order. (4) The Association for Improving the Condition of the Poor is about to erect a sea-side sanatorium for children near Coney Island.

Dispensaries.—1. Presbyterian Hospital. Several years ago Dr. Shively, at the Presbyterian Hospital Dispensary, recognized the importance of especial attention to the dispensary cases of tuberculosis, and considerable interest has been taken in these cases there, although no regulation of their home surroundings has been attempted.

2. Post-Graduate Hospital. At the Post Graduate Hospital, Dr. Russell has been carrying on a very careful and successful system of management of a considerable number of tuberculous out-patients. His general plan is one of superalimentation with milk and eggs (sometimes as high as 5 quarts of milk and 18 eggs a day) with very free daily catharsis ℥i to ℥iv of castor oil, supplementing this with an emulsion of mixed fats, and, where possible, with a month of preliminary treatment in bed, upon a strictly milk

diet. This class is limited to those who are able to afford this extra food, the cost of which is considerable, and the scope does not extend to systematic supervision of the home life.

The value of this work has been very great in demonstrating the practicability of the successful treatment of pulmonary tuberculosis in New York City, even in advanced cases.

3. Vanderbilt Clinic. About January 1, 1903, through the support and cooperation of Dr. James, there was instituted at the Vanderbilt Clinic, under the writer's supervision, a system of more careful management of these cases of tuberculosis than had before been customary. The main points in this system are special histories and regular weekly records of these cases, detailed oral and printed instructions in regard to this disease, free distribution of sputum pouches, and a visiting nurse, who makes written reports of the home conditions and cooperates with the physician to make these conditions conform as far as possible to the hygienic requirements for the treatment of this disease. Through this visiting in the homes, it is possible to supplement the dispensary treatment and to recognize the need for charitable assistance or hospital care. In other words, each patient is followed up and every effort is made to make use of the different agencies for helping them of which we have already spoken. At the Vanderbilt Clinic this work is done as a part of the regular duties in the Division of General Medicine, and there is no separate class for tuberculosis. Of late, it has been supplemented by arrangements for visiting nurses from the training schools of the Presbyterian and Roosevelt Hospitals, and the general management is now in the hands of Dr. Linsly R. Williams.

4. Bellevue Hospital. A few months ago it was proposed by the President of the Board of Trustees of Bellevue and allied hospitals, Dr. J. Winters Brannan, to take up this special tuberculosis work in connection with the out-patient department of these hospitals. The task of organization was put in the writer's hands, and about the middle of December last a special tuberculosis class was started in the Bellevue Hospital Out-Patient Department.

The general plan is the same as at Vanderbilt, but more adequate resources have made its elaboration possible. All the means spoken of in connection with Vanderbilt Clinic are made use of, and, in addition, arrangement has been made for the supply of milk and eggs from the hospital store, as a part of the treatment. Besides this, there are now being erected upon the hospital grounds, tent cottages for the use of such patients whom it is desirable to keep in bed, under observation, for awhile, or for whom a few weeks' training in habits, mode of life, etc., seems advisable.

Also, the close proximity of this hospital to the office of the Superintendent of Out-door Poor makes the use of the different hospital facilities at his disposal a very easy matter. The nursing is done by the pupil nurses of Bellevue Hospital, under the direction of a head nurse with large experience in district visiting. In the medical work, able assistance is rendered by Dr. Haven Emerson and Dr. E. L. Trudeau, Jr.

I think it is no exaggeration to say that this system gives to Bellevue Hospital the distinction of sharing with the Phipps Institute of Philadelphia the honor of possessing the most adequate means of dealing with the consumptive poor in their homes that exists in this country.

5. The Health Department Dispensary. The Health Department has erected a special dispensary for tuberculosis, modeled after those of France. This is a separate building, with different rooms for consultation, examination, throat and X-ray work, and all the requirements for the diagnosis and treatment of such patients. This dispensary is very shortly to be opened, and in connection with it will be used all the splendid and extensive organization of this department in regard to home inspections, visiting nurses, printed circulars, hospital accommodation, etc. There will be evening classes, which will be of very great value to such patients as are able to work, and therefore cannot attend regularly at the usual dispensary hours. The promise of this institution is very great, and its usefulness and value to the community will add considerably to that of the Health Department, great as we have already seen that to be.[1]

As far as I am aware, this completes the list of dispensaries in this city which attempt a satisfactory treatment of their tuberculous patients. Now that the practicability of such treatment has been established, it could easily be undertaken, in some measure, at least, by every dispensary. Just as soon as that condition of affairs obtains, the ultimate solution of our tuberculosis problem is very near at hand.

MANAGEMENT OF DIFFERENT CLASSES OF CASES.

Differences in several conditions modify this management.

1. *Stage of Disease.* Whether early, moderately advanced, or far advanced.

2. *Economic Conditions.* Such as ability to work, confinement to bed, and the resulting conditions of self-support, or complete or partial dependence upon others.

3. *The Character of Housing.* Whether in lodging or furnished room houses or in tenements; and whether these tenements are passably sanitary or totally unsanitary.

Patients in the early stages are generally able to work, and therefore self-supporting. But this work is often too arduous and very harmful to the patient. This condition of affairs should not be allowed, if possible. Change to more favorable occupation should be effected, or the patient should be sent away to some suitable sanatorium or rural hospital. These are the cases whom we

[1] At the time that this article was written the writer was ignorant of the admirable work of the Tuberculosis Clinic at the Gouverneur Hospital. This has been in operation since July, 1903.

may reasonably hope to improve or get well, and very careful assistance should be given to them, to let them at least have a fair opportunity. It is not fair to advise them to go to the country or to change their work, and then dismiss all responsibility toward them. It is generally absolutely impossible for these people to follow this advice, unless assistance be given them. This can very often be obtained from some of the charitable institutions we have considered. If they stay home, we should look after their home conditions and in some way provide extra nourishment, for this is *the treatment* of the disease, and we, as physicians, are responsible for it. It has been a matter of great surprise and encouragement to me to note how often these patients do well under the dispensary management such as we have described, and during the past year not a few cases of arrested disease have been noted.

The Moderately Advanced Cases require the greatest judgment and skill. As a general rule, they should not work. The question of hospitals immediately comes up, and Seton, Riverside and Metropolitan are the ones best adapted for these patients. The patients of this class should never be sent far away from home, unless ample provision is made for their support in every contingency. Too often, a burst of charity sends them to the Adirondacks, or elsewhere, and leaves them stranded there, an additional burden upon an already overtaxed community.

Unwillingness on the part of the patients, or lack of room in the hospitals, usually makes this method of disposal unavailable, and, as they cannot or should not work, they, with their families, must become either partially or wholly dependent upon outside assistance, in order to live. As in these cases there is still some good hope of improvement, extra nourishment and sanitary surroundings must be added to the bare necessities of living. It is in these cases that the various agencies of relief are of the greatest benefit.

Where there is any question of the actual necessity for outside assistance, the case should be referred to the Charity Organization Society or the United Hebrew Charities for investigation as to the resources, family connections, past record in habits, thrift, etc., before indiscriminate help is given. This question being satisfied, the case may either be left in the hands of one of these organizations to provide necessities and extra food, or this assistance may be obtained directly from other relief agencies, such as the Association for Improving the Condition of the Poor, the different church charities, the diet kitchens, the Straus milk depots, etc. This help should always be given, however, under medical supervision, in order that the needs of each patient may be properly supplied and in order to insure to these different societies the distribution of their help in such manner that it will do the greatest amount of good.

All Advanced Cases are better cared for in suitable hospitals, and to secure their admission should be our first endeavor. This is particularly true of bed-ridden cases, for whom, of course, dispensaries cannot provide, and whose progressive weakness and loss of feeling of responsibility make the proper care of the sputum impossible. If such patients persistently refuse to go willingly, they should generally be referred to the Health Department for compulsory removal.

Cases not sent to hospitals must be watched carefully, especially by nurses, and distressing symptoms relieved. On account of the insufficient supply of extra food available for more favorable cases it is our usual custom to withhold this part of our treatment from cases evidently hopeless.

Differences in Housing Conditions affect the management of all three classes of patients. Light, clean, well-ventilated tenements can readily be converted by an intelligent nurse into very fair home sanatoria. When such homes are found, it influences considerably the decision upon the necessity for hospital care.

Unsanitary tenements, however, must not be so used. Either the family must move to more favorable quarters or the patient must go to a hospital or sanatorium. The moving may be effected by financial aid from the Charity Organization Society, the United Hebrew Charities or the Association for Improving the Condition of the Poor, when such assistance is necessary. If any violations of law exist, they should be reported to the Tenement House Department, and the Health Department should be notified of the removal, in order to disinfect the premises.

Lodging-house cases and many furnished-room cases may be removed to hospitals by authority of the Health Department, and this should be done. It is impossible to exercise any supervision over such cases from the dispensary. They come back for observation very irregularly, the nurse cannot find or follow them, and therefore home instruction is impossible. These patients, floating about from one lodging-house to another, with no fixed abode or sense of responsibility to their fellows, constitute one of the most prolific causes of the spread of this disease, and one that it is impossible to counteract, as long as they live under such conditions. The welfare of the community demands and justifies their compulsory removal and retention in suitable hospitals.

This completes our review of the possible methods of management of these cases of tuberculosis among the poor. My ideas concerning our responsibilities, as physicians, toward them are already apparent. We must treat these patients properly, and follow up this treatment to its logical conclusion.

To tell them to go to the country is simply a waste of breath. To simply prescribe medication, is to give a "stone," when their need is for "bread." To advise fresh air, good food and light work, without providing these things, is a hollow mockery.

The proper treatment of these cases involves,

as we have seen, a great expenditure of time, thought and skill, in directions including the entire social, as well as physical condition of the patient. The dominating control of all phases of this treatment should not be delegated to any charitable society, but should lie with the patient's physician. In order to hold this effectually, this physician must study and understand all the underlying conditions, which we have seen to be much more complex than simply those of physical signs and medication.

It is true that there is great advantage to be derived from better knowledge of the social aspects of any disease, but in none is this knowledge so essential, or its application so remunerative, as in tuberculosis. Thinking men of experience are coming more and more to the agreement that, under proper conditions and proper management, tuberculosis is a preventable and curable disease in any climate, even in that of the City of New York; and to any who care to study and to understand this disease, the prospect of success seems brighter than in any other of the great problems of preventive medicine of to-day.

It would be impossible for anyone to study this tuberculosis problem without being deeply impressed with the tremendous influence that has been exerted upon it for several years by the untiring efforts of two men. These men are Dr. Hermann M. Biggs and Dr. S. A. Knopf. In every phase of a most difficult struggle they have stood together, and often alone, with both profession and laity combined against them. But, by steadfast adherence to their firm convictions, they have accomplished many of their ends, and in so doing, have placed this whole community under a lasting obligation to them.

I cannot more fittingly close this discussion than by expressing the sincere wish that at least some of the spirit of their energy and enthusiasm in this vital question may be infused into each one of their fellow-practitioners here present.

The writer wishes to express his indebtedness for much information to the officers of the various institutions here considered and also to "A Circular to Physicians," issued by the Health Department, "A Handbook on the Prevention of Tuberculosis," published by the Charity Organization Society and *The Tenement House Problem*, edited by DeForest and Veiller.

550 Park Avenue.

The Action of Nicotine.—In studying the nicotine tolerance in rabbits, R. A. Hatcher (Am. Jour. Physiol., April 1, 1904) found that this poison is very uncertain in its action. While death is due to failure of respiration, artificial respiration, if effective at all, must be begun before the centers show evidence of marked depression. The stimulating effects of heat are undoubtedly useful in combating the toxic effects. No cumulative effects can be seen when nicotine is given daily for several days. Nutritional disturbances follow its prolonged use, by the appearance of ulcers at a point some distance from the seat of injection, disappearing with the cessation of its use, and reappearing upon resumption. No antitoxic serum has been found.

A REMARKABLE CASE OF GASTRIC CANCER: SEPARATE INVOLVEMENT OF CARDIA AND PYLORUS: GAIN OF 35 POUNDS IN WEIGHT WITHIN THREE MONTHS OF DEATH.[1]

BY G. W. M'CASKEY, A.M., M.D.,

OF FORT WAYNE, IND.

The following case presents features which appear to render it worthy of a separate record as it has a bearing on some interesting questions relative to diagnosis. The case is included in another paper reporting six cases of cardio-esophageal cancer.

The patient, Mr. G., aged forty years, was referred by Dr. James Wilson, of Wabash, Ind., February 7, 1902. He gave a history of "stomach trouble" of about one year's duration. The first symptom was pain after eating in the region of the stomach, also in the back between the shoulders especially in the right side. A few weeks later he began to have excessive gas formation in the stomach, both this and the pain being most aggravated almost immediately after eating. This second symptom had been persistent but rather worse for the six weeks preceding my examination. He had vomited only a few times, and this had never been in close relation to meals.

Five months after the beginning of the symptoms, he had a severe attack of "gastralgia" following dietetic indiscretion, and from that time on the pain was more troublesome. It was also more severe when the patient was on his feet, especially if exercising much, and lying down at night would give relief. There was a tendency to constipation but never any sign of melena; he was greatly troubled by intestinal gas. His normal weight was 220 pounds, but he had lost about 45 pounds.

Upon physical examination the liver was found to be slightly enlarged, rather firm on pressure, but not tender and quite irregular on the margin. The stomach was not enlarged. Examination otherwise negative. Test-meal revealed the absence of free hydrochloric acid but strong biuret reaction; lactic acid was present, but no Oppler-Boas bacillus. Uranalysis gave no important indications except in the presence of the ethereal compounds of skatol and indol. Later in the case, in June, before my last examination, there appeared a little albumin and bile acids.

The blood examination showed 15,000 leucocytes at the first examination, and 10,000 a week later. The blood was concentrated containing 6,000,000 red cells upon first examination and 5,500,000 on the second with about 110 per cent. of the normal amount of hemoglobin. There was a slight mucous colitis.

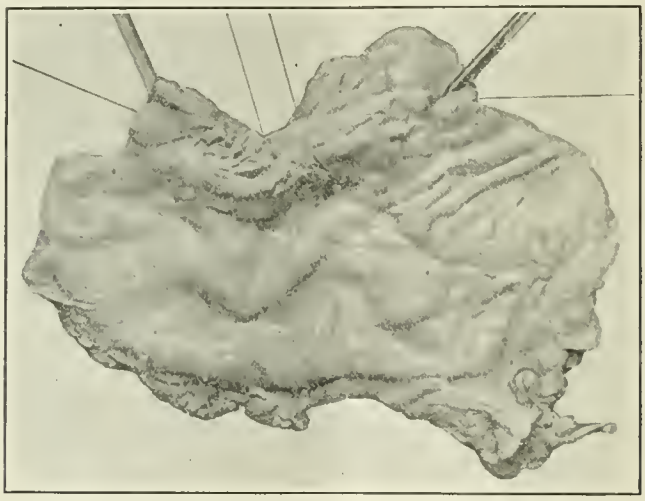
It is perhaps worth noting that the patient had grip three years previous, and "walking typhoid" two years prior to examination, and had not been perfectly well since the last mentioned illness.

[1] Read before the Allen County (Ind.) Medical Society.

The patient was under my personal observation and treatment for a few weeks, and the stomach conditions improved somewhat, a little free hydrochloric acid appearing once or twice. A few weeks later the stomach symptoms suddenly left him, his appetite became morbidly voracious, and he ate with impunity enormous quantities of meat, bread, potatoes and other solid food, and in three weeks his weight increased thirty-five pounds. There was no dropsy at that time and the phenomenal increase of weight was clearly due to tissue building of one sort or another. The gain did not last, however, the stomach symptoms recurring in three or four weeks; a little later marked jaundice supervened: still later, about four weeks before death, which occurred in November, five months after my last examination, general dropsy developed.

The disappearance of stomach disturbance, the voracious appetite and the rapid increase of weight are certainly remarkable phenomena in the case of a patient who died of cancer some three months later, as the autopsy showed that there must have been considerable involvement at that time of both the stomach and liver. It would constitute a disturbing factor in the diagnosis if such a case would present itself during the progress of such phenomena. While I did not see the patient during or after this occurrence, I inquired closely concerning the patient's appearance, and I am informed by his attending physician that along with the increase of weight, rotundity of form, etc., there was not a corresponding approach toward appearance of health. This, from a diagnostic point of view, is a saving clause.

Fig. 1.



1. Pylorus; 2 and 3. The space between these lines was not indurated, and was apparently free from involvement, although the shading in cut tends to give a different impression; 4. Cardiac orifice.

At the time the patient left me, I had expressed to Dr. Wilson a strong suspicion of cancer and was considering the advisability of recommending an exploratory procedure.

At the autopsy, which was made by Dr. Wilson, the liver was found to be markedly enlarged with a diffuse carcinomatous process, while the stomach was apparently normal, excepting in the pyloric and cardiac regions where it was much thickened by neoplastic formation. The middle part of the lesser curvature was almost, if not entirely free from the morbid process for perhaps an inch or thereabouts, the pyloric and cardiac neoplasms gradually shading off in thickness toward this point. Sections of the neoplasms showed typical adenocarcinoma. The stomach, which was removed entire and sent to me by Dr. Wilson, was apparently normal in every other respect, and was not greatly enlarged, its capacity being 1,200 c.c.

In reviewing the case in the light of the autopsy, it would appear probable that the cancer of the liver was the primary process, the preponderance and priority of pain in the hepatic region, while not very marked tends to support this view of the case. On the other hand, it is quite possible that the gastric cancer was primary though very slow in its evolution and that the liver was the last organ implicated. Anatomical and physiological considerations tend to support this view, as the movement of fluids by which metastatic processes occur does not take place from the liver to the stomach, but from the stomach to the liver. The accompanying cut indicates the area of carcinomatous invasion, and so far as I know such a distribution is rare.

Hahnemann Medical College.—The fifty-sixth annual commencement was held May 21, a class of 66 being graduated.

POSTPARTUM TUBO-OVARIAN ABSCESS CAUSING HYDRONEPHROSIS.[1]

BY A. ERNEST GALLANT, M.D.,

OF NEW YORK.

The case from which the specimen herewith presented was removed, afforded several points of unusual interest, not only from a diagnostic standpoint, but also in relation to its mode of development, the plan adopted for its removal, the after-care and rapid convalescence.

1. The advent of labor was announced by rupture of the membranes, inefficient pains; manual dilatation of the cervix, and final delivery by high forceps; child strong and healthy.

2. Rising temperature on fourth day, with no vaginal evidence of infection.

3. A rapidly forming tumor developed on right side during seventh and eighth days, pressing on ureter, causing hydronephrosis with marked diminution of urine, and thought to be due to a prolapsed kidney.

4. No relief by posture. Aspiration at first of clear urine, followed by pus, tumor diminished in size to one-half, and passage of 64 ounces of urine during next twenty-four hours.

5. Cystoscopy showed bladder somewhat inflamed, clear urine from both ureters.

6. Tumor refilling; increasing pulse and respiration deemed good reason for operation. Through lumbar incision, splitting the muscles, a flattened kidney was made out, and an intraperitoneal tumor dissected from the undersurface of the liver and diaphragm; attached below by a broad pedicle to the pelvic brim. Not wishing to elongate the lumbar incision, the tumor was emptied through a two-inch median incision, and proved to be a tubo-ovarian abscess.

7. Massage begun the day after operation, and continued daily; pulse, temperature and respiration fell during anesthesia and never rose above 99.5° F. afterward. Primary union throughout. The patient was out of bed on the fifteenth day, and rapidly regained her former strength.

8. The application of a specially designed corset, for the prevention of hernia and visceral prolapse. Also gauze vaginal tamponade of the vagina after the uterus had entered the pelvis, to assist that organ in resuming its proper relation to the bladder and the prevention of uterine displacement.

Mrs. E. M., *September* 13, 1903. Premature rupture of membranes, manual dilatation of cervix; high forceps; living child.

September 17, fourth day, post partum, Dr. Moss reports temperature 102° F., lochia normal, uterus contracted, not tender. Cannot account for fever.

September 21, eighth day, Dr. Moss reports that during past two days a tumor has been rapidly forming on the right side, bulging the anterior wall forward. Temperature 102° F., pulse 128. Examination shows a moderately tense, fluctuating tumor, extending from under the ribs, to the pelvic brim of the right side, also causing bulging in the right loin. Cannot be felt through vagina. Lochia stopped; no discharge, no odor; uterus on level with brim, moderately firm, os externum gapes, lacerated into right fornix; left fornix soft and pliable. Urine markedly diminished, 19 to 20 ounces during past twenty-four hours. Diagnosis: Hydronephrosis, probably due to prolapsed kidney. Foot of the bed elevated, in hope of relieving retention. Bladder irritable.

September 22, ninth day, post partum, trocar introduced just below twelfth rib in anterior axillary line, and clear urine dribbled away; trocar reintroduced a little lower and posterior, half its length, and about 24 ounces of clear urine of a very dark, smoky color came away; trocar pushed in full length, with pressure, was followed by five to six ounces of pus, and reduced the tumor to one-half its former size. During the following twenty-four hours, 64 ounces of urine were passed, sp. gr. 1.012, normal color.

September 23, tenth day, post partum, cystoscopy: Bladder interior somewhat congested. Several small congested areas on lower and posterior surface, attributed to the catheter, which had been used during the preceding week; clear urine from both ureters; right ureteral opening edematous. 1 P.M., 26-90-98.4; 9 P.M., 24-94-99.

September 24, 8 A.M., 26-94-99; 8.30 P.M., 30-108-99.

September 25, twelfth day, post partum, 6 A.M., 30-110-98.2; 12 N., 30-120-99.2.

Dr. Moss reports tumor refilling, and on account of increasing pulse rate and rapid breathing it was decided to operate for the removal of probable pyonephrosis, with kinking of the ureter.

Operation began at 3 P.M., Dr. E. W. Peet assisting; Dr. Plympton administering ether. Patient on kidney bag; an oblique incision was made from the edge of the twelfth rib to the anterior superior spine; the muscles split layer by layer; the twelfth nerve pushed aside, and after tearing through the fatty capsule the kidney was found well up above the twelfth rib, firmly fixed in its normal position, moderately enlarged, and *flattened*, being only about half as thick as normal. Further examination showed the tumor to be wholly intraperitoneal; the peritoneum was opened, the tumor, by blunt dissection, separated from its attachment to the under surface of the liver and diaphragm posteriorly; and when free settled downward and inward in the abdominal cavity. On following it down it was found attached to the pelvic brim by a broad pedicle which could not be reached through the posterior incision without extending it through muscles. I preferred to close the lumbar wound, and then made a two-inch median incision just above the pubis; drew the tumor to this opening and drained off more than two pints of pus; delivered the sac, which was then recognized as attached to the right broad ligament,

[1] Presented to the American Urological Association.

and involved the tube and ovary of that side. The stump was sutured; dropped back, and the median wound closed. Ether 1 hour 40 minutes, operation 1 hour 29 minutes. Highest pulse 140, at close of operation 112. 8 P.M., 30-108-99.

September 29, fourth day, sutures removed; primary union throughout.

October 10, fifteenth day, out of bed one hour.

October 21, nurse discharged. *October* 28, corset put on.

Note.—April 21, 1904. Dr. Moss reports that the patient's health has been excellent; and, excepting some irregularity of menstruation and a sense of stiffness and soreness in the lumbar region on lifting, is as well as can be. Advised to resume calisthenics daily.

60 West Fifty-sixth Street.

ETHYL CHLORIDE AS A GENERAL ANESTHETIC.[1]

BY A. F. ERDMANN, A.B., M.D.,
OF BROOKLYN, N. Y.

Probably most American anesthetists and surgeons share the experience and opinion of the writer of a paper on surgical anesthesia (*Journal American Medical Association,* Dec. 5. 1903, p. 1400) who says, "My experience with ethyl chloride as a general anesthetic is *nil,* but from the data at hand I am inclined to class it with the more dangerous anesthetics, and would expect it to be especially dangerous in cardiac and respiratory troubles." It is certainly true that an astonishingly small proportion of such practitioners are at all familiar with this most valuable anesthetic agent. The writer, after diligent inquiry, has been able to find only one surgeon in Brooklyn who is really using it. In Manhattan there are only a few more. In Philadelphia it is used at the University Hospital. Cumston in Boston has now made use of it in 350 cases. Allen at the Massachusetts General Hospital has employed it in about 60 cases. There is a report of its use in the Medical Association, Chicago, 1900, xxxii, p. 710. Nor as yet have the English surgeons generally taken kindly to ethyl chloride. But on the continent, in France especially, many are turning from both nitrous oxide and bromide of ethyl to this recently anew exploited systemic anesthetic agent.

This anomaly appears still more strange when one considers what claims are made for ethyl chloride, and upon what facts the French, Swiss and Germans base their good opinions. In a word, it is maintained that ethyl chloride is a relatively safe general anesthetic, exceedingly simple in its use, particularly pleasant to inhale, surprisingly rapid in both its action upon the body and its escape from it, and happily much less liable to those unpleasant sequelæ, both serious and simple, which so often follow other anesthetics. The fact that some 30,000—estimated—anesthesias have already been given should be enough to ensure it a favorable attention, and when one considers in addition all the operations for which it has been successfully used he is less surprised that some anesthetists do, and more surprised that some do not make use of ethyl chloride. Ware,[1] of New York, for instance, has employed it 2,000 times, chiefly in minor surgery on women and children. Mazzoni[2] (Rome) has done laparotomies and a vaginal hysterectomy. Malherbe[3] (Paris) tells of a mammectomy and a herniotomy where ethyl chloride was used. In Birmingham[4] they do operations for strabismus under its influence. At Guy's Hospital[5] iridectomies are not uncommon. *La Presse Médicale* June 29, 1901, reports enucleations and operations for muscular advancement where it was used. At Innsbruck[6] they had no bad results in employing it with patients having heart lesions and respiratory affections. The pulse remained normal in a case of marked mitral obstruction reported by Nové-Josserand.[7] This same surgeon operated in the presence of advanced phthisis. The Swiss surgeon, Bossart,[8] reports similar cases. Patients have been cyanotic and dyspneic, requiring tracheotomy. Reboul[9] tells of a child four and a half years of age, extremely feeble after a prolonged typhoid fever, in whom some abscesses were opened. A number of patients had a temperature of over 39.5° C. and some were suffering from emphysema and arteriosclerosis. An operation was done during the seventh month of pregnancy. A number of interesting experiences in midwifery are described by Lepage and Lorier,[10] and by Burnet (*The Medical Press, December* 10, 1902). I have myself had excellent results in forceps cases.

A lad, ten years of age, took it in all 33 times; another boy, twelve years of age, 12 times, and a woman of fifty-six years took it ten times.[8] In neither an infant of three months nor a patient of seventy-nine was there any untoward symptom. A child[2] three years of age was given 120 c.c. during an operation for an impacted urethral calculus which lasted over an hour. What a list! Again and again the reporters say that there was no alarming symptom or that there was not the least cause for alarm. In *Guy's Hospital Gazette,* April 11, 1903 one reads, "In the presence of grave hemorrhage the ideal anesthetic is A. C. E., or Kelene followed by A. C. E."

Perhaps one of you will now be willing to let me use ethyl chloride for one of your cases. Maybe it is an office case: an abscess is to be opened, or a vaginal examination is to be made under anesthesia. Of course it is best that the patient has not eaten just previously; yet if she has and vomiting does occur it will probably be only slight and transient. Clarke (Brooklyn) says his patients have never vomited. Ware's hour at the Good Samaritan Dispensary (New York) is in the early afternoon and he anesthetizes his patients as they come, even just from dinner. Perhaps the patient objects to lying down, or may be the operation is to be a tonsil-

[1] Read before the Associated Physicians of Long Island, January 23, 1904.

otomy or other throat operation and the Rose position is not desired; you may have him anesthetized sitting in a chair, if you wish that position, and know that this is a common practice. But it will be prudent to have him on his back. A syncope is reported from Wolverhampton when the patient sat up during an operation. McCardie[4] (Birmingham) and a French dentist had similar mishaps. It will be wisest to observe the ordinary precautions which are taken in any anesthesia.

One is now ready to choose an inhaler. But this is not such a simple matter, for there are many of them. It may be a plain gauze compress, costing next to nothing, or an elaborate so-called "Minimum," which is sold for 120 M. It may be comparatively open, as Ware's model, or tightly closed, as the "cornet" used by Fromaget[12] or the cornucopia described by the author in his paper, *The actual Schleich narcosis* (*Brooklyn Medical Journal,* June, 1899). Or it may be one less closed, as some form of the Clover[13] or Ormsby bag apparatus, or less open as the Breuersche Korb,[11] after whose design Kny-Scherer are making an American model. Between these extremes there are many others. The Schönemann as well as the Seitz, universal mask; Brodtbeck's celluloid mask with an iris diaphragm. Juilliard's large ether mask has been used. For mixed anesthesias a serviceable form is this simple modification along well-known

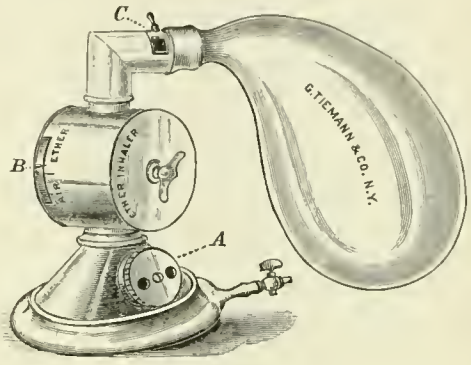
ERDMANN'S CORNUCOPIA INHALER

lines of the Allis inhaler (*Medical Record,* Jan. 23, 1904). Since this paper was written I have seen Goldan's (N. Y.) apparatus. The ethyl chloride is confined on gauze in a tube between valves so that there is at once an "open" method of administration and an absolute prevention of waste.

The gauze compress and the towel cornucopia are simple and clean, and save the ethyl chloride; but they, as well as the English bag apparatus—with these would have to be included the several American models which are just as good—necessitate an essentially close method. The Breuer form is a good one, but the construction of the



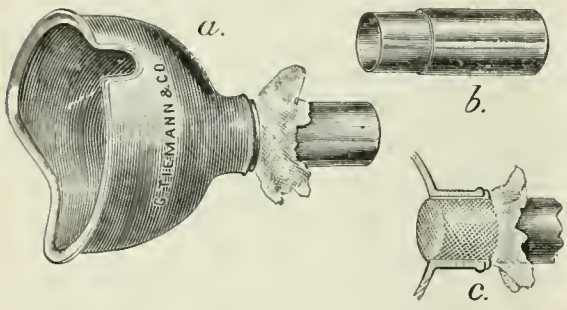
valves forbids cleansing and, besides, it is as yet a very expensive apparatus. The author prefers Ware's[14] mask, because it is simple and inexpensive, gives plenty of air and can be readily cleaned. However, when the patient can bear a more concentrated vapor, the most brilliant results are obtained with a "close" mask. This is especially true in obstetrical work when the patient must be eased quickly yet transiently. I have had great satisfaction on several occasions in noticing how promptly the pains were relieved and how very wide awake the patients were during the intervals.

Of the half dozen preparations of the ethyl chloride which can be purchased only two are as yet generally used. Probably unless the author specifies, that form known as Kelene is always meant. Kelene is the trade name for the product of the Société Chimique des Usines du Rhône, The Monnet tube in which it is put up is convenient and enables the anesthetics to follow easily Ware's direction to "spray intermittently." Dr. Henning, in Berlin, manufactures a most excellent product which is known as "aetherchloratus narkosi," or simply as Henning's ethyl chloride. This can be obtained as yet only in a container which cannot well be inverted. The small tubes which Henning makes containing only 3 to 5 c.c., ought to be very handy for one who prefers the close method and mass doses. These others, Antidolorin and Anodynone, have been used so far as I can learn only by Cumston, who reports favorably upon them in an excellent article in the *Boston Medical and Surgical Journal,* January, 1903. Clarke (Brooklyn) uses the Bengué product. Any pure ethyl chloride can be used. The author does not mean to say that only the two prominently mentioned are pure forms, but merely reports what he has noticed in his investigation, that they with the Bengué product are considered to be the best.

Ethyl chloride is decidedly pleasant; it is

neither cold nor pungent, does not cause any choking or coughing and only in a very large dose might it cause one to hold the breath. Sometimes if the gauze in the Ware mask is not thick enough some of the spray will fall upon the face and cause the patient to shrink. But this is only a momentary unpleasantness and can be entirely avoided by care in preparing the mask. On the other hand, if the gauze is too thick and the capillary opening in the tube large then a hoar frost readily forms on the gauze and occludes the opening. In both such instances one must know how to adapt the spray to the thickness of the gauze diaphragm. If the gauze compress or the cornucopia is used care must be exercised not to allow the fluid to touch the face. That it is comparatively harmless, however, the author knows, for he once sprayed a drop into his own eye without any injury resulting.

There are really only two methods of exhibiting ethyl chloride and these differ only in this, that whereas Ware's apparatus allows the anesthetist to give it drop by drop, as it were, and thus suit the amount to the patient—to individualize the patient—all other forms are meant to re-



ceive a mass dose, on the assumption that 2½ c.c. is the smallest amount which will narcotize any one. Some operators give 5 c.c. or even up to 15 and 20 c.c. at once.[25] I cannot feel that this is a wise procedure. If one follows Ware's method he will probably find, unless he is unusually proficient, that he will take a longer time and use more of the anesthetic than when a close method is followed. But he may feel that he is working along more rational lines and because he is better able to treat a patient's possibly greater susceptibility, he can give more accurate doses and will feel safer. After a few inspirations the pulse rate may become somewhat heightened. Usually a rapid pulse continues such; a slow one may be accelerated. Many times there is no change whatever. It is thought by some that the acceleration is due to a too highly diluted vapor, and that the patient becomes nervous because he does not go under fast enough. The tinnitus aurium and sounds of whistling and hammering which may be present at this early stage might easily excite persons already apprehensive of danger. Or, again, a dose relatively too large may send the pulse up. Dumont in particular, calls attention to this. All observers agree with McCardie[4] that the pulse may be disregarded so long as the respirations remain full and strong.

Is there any arterial hypotension? H. C. Wood (University of Pennsylvania) in the 1892 *Dental Cosmos,* basing his opinion solely upon some animal experiments, said there is always a fall of the blood pressure due to a direct depression of the heart. But he used an admittedly concentrated and suffocating dose, and induced some of the anesthesias even by injecting the ethyl chloride directly into the jugular vein. König[15] records the same effect but does not consider it to be so marked and ascribes it especially to a concentrated vapor: and even then he found it less true of the monkey than in dogs. Malherbe and Rubinovitch[16] using the Potain sphygmomanometer on 24 human subjects also sustain these findings: in 22 instances there was arterial depression and the number of the heart beats increased apace with the lowered tension. Ruegg[17] of Basle maintains that a dilute vapor dilates the blood-vessels while a concentrated vapor contracts them and increases the heart's action. The weight of clinical observation is against these deductions from animal experiments. The heart is not usually affected; if it is, the temporary change may be ascribed to the causes already mentioned and quickly ceases when the anesthetic is stopped. Rose[18] (Bristol) did not find any variation worth recording in the four anesthesias to which a woman submitted whose heart sounds were observed by a loud double mitral murmur. Bossart[8] (Aaran) reports three cases of compensated heart lesion all acting favorably. Hacker (Innsbruck) says he had no bad results in a case of fatty degeneration. It is a common experience to begin with a pulse at 120—I had one at 132—and find no change during a short operation.

But the effect upon the respiration is more marked even from the beginning. There is no irregularity, but a deepening of the thoracic excursion, an augmentation of the force and usually some increase, a regular increase in the rapidity. But it does not become shallow or slow. Sometimes a soft snoring is observed. Several cases are reported of a temporary inhibition of the breathing. These may have been true apneic pauses, or have been due to atonic spasm of the chest muscles or of the diaphragm. They quickly passed away when the mask was removed. In the main Nové-Josserand's[7] observation will hold true, that the respiration remains calm, regular, deep, sometimes a little stertorous, but is usually not greatly modified.

Especial attention must be directed to a frequently observed phenomenon. If the patient begins to snore he is ready. This effect is so commonly produced that McCardie counts it as one of the cardinal signs of a fully established anesthesia. If in addition to this the muscles are relaxed and the conjunctival reflex is lost, while the pupil is moderately dilated and the eyeball is turned to one side, then it is only time lost to delay any longer.

Yet it is not necessary to wait for all of these

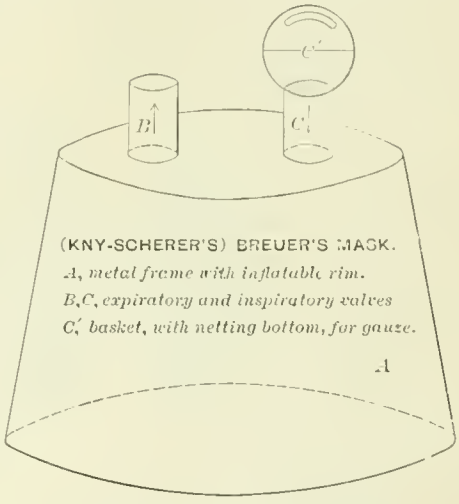
signs. Sometimes there is not complete muscular relaxation, nor are the conjunctivæ always insensible. There may even be contracture of the muscles somewhat as in the cataleptic state. When this occurs Seitz[19] (Constance) says it is a true second stage and corresponds to that brief moment in an ether anesthesia which is called the *aetherrausch,* and like that can be utilized for a short operation. The patient is not really anesthetized as we use the term, but he has been *analgesized,* if I may coin a word, he does not feel the pain although he may resist the attempt to operate. I have had several cases which illustrate this. One was a simple perineorrhaphy. The patient consumed more Kelene than I had expected, so that just as she was ready—cataleptic—the anesthetic tube was emptied unfortunately. I thought that the stitch could be taken anyway, but as she squirmed some when the needle touched her, it was thought best under the circumstances not to persist. I was greatly chagrined when she said a minute later that she had not felt any pain whatever. The other case was even more pronounced. Suffice it to say that an infected finger was opened while the man was struggling. When he regained consciousness he had no recollection of any pain. He said he felt that something was being done to his finger but he did not know what.

It is a common practice to exhibit the ordinary dose (2½ to 5 c.c.) after a "close" method and to operate after a few minutes even if the patient seems to feel. If once the breathing has become rapid, especially if snoring in character, the pupil moderately dilated, and the patient has made purposeless movements or has stiffened the whole or a part of his body, he is insensible to pain and the short operations may be done in good conscience. One will find that in a complete anesthesia the muscles do relax sufficiently to permit operations in which this condition is required. A study of the operations already reported, laparotomies, amputations, the reductions of old dislocations and others shows that such must be the case.

Yet sometimes the muscles will not relax sufficiently, or there is too pronounced a stage of excitement. Ware (New York) reports 5 per cent., Girard[20] (Toulon) 6 per cent. of failures. Reboul had to change the anesthesia in five instances. McCardie records some failures with the Breuer mask, but says that he is able to anesthetize any one, even an alcoholic, with the Ormsby inhaler.

Nervous patients usually make some erratic motions or cry out incoherently. Alcoholics are notoriously bad subjects for any anesthetic, and ethyl chloride is no exception. Yet it does seem that they struggle least when that is used or even not at all, and they can be quieted absolutely if a preliminary hypodermic injection of morphine is given. Even if there has been excitement and struggling they seldom are aware of it afterward as being caused by the anesthetic. They remember it as from a dream. Sometimes the dreams are very real. A patient of the author laughingly said he had imagined he was being assaulted by two robbers and that his struggles were to free himself. This was a near approach to the nightmare of which some occasionally speak.

Much more usual is the experience of passing through pleasant scenes and enjoyable occasions. Girard[20] tells of a young woman who both asked and answered questions during the course of the operation. Strangely, upon awakening, she recalled only a vivid dream of having been transported far away into and through deep woods and flower gardens. He also interestingly narrates his own experience. He dreamed that he was visiting again some Alpine mountains and beheld a marvelously beautiful sky and sun. When he awoke after the short operation he sat up on the table rubbing his hands, surprised at his position and disbelieving that the operation had been done. He was able to get down without any assistance; had no unpleasant feelings except a pasty taste and was able to direct a scheduled operation.



(KNY-SCHERER'S) BREUER'S MASK.
A, metal frame with inflatable rim.
B,C, expiratory and inspiratory valves
C' basket, with netting bottom, for gauze.

There would seem to be some reason for taking the precaution of having a third party present when anesthetizing women, for two anesthetists have already been accused of having made criminal assaults. It is not indeed very unusual, when the operation is upon or about the genitals, to notice that the dreams seem to be of an erotic nature. In a recent case the author observed an annoying priapism. A report is made of another such instance in which even the orgasm took place. These are comparatively rare observations, to be sure, and are mentioned only that they may be expected.

Whatever the character of the unconscious or subconscious state, or however much the patients speak or move one does not have to fear the rebuke not infrequently heard after a gas anesthesia, that the pain was all felt but the power to manifest it was absent. Once under the anesthetic the sense of pain has disappeared, though the tactile sense may remain. A curious fact is that this analgesia continues for some time after consciousness has returned; it may be even for ten and twenty minutes.[26]

The awakening is rapid, sometimes within a few seconds after the mask is removed, and generally, according to the quantity of the anesthetic inhaled. It is a return to full consciousness. The eye is wide open, the senses are active, there is neither dulness of hearing nor a dimmed vision, the aspect of the face does not indicate the presence of an anesthetic; there is no odor on the breath, perhaps a pasty taste which a swallow or gargle of water quickly removes, rarely a headache and vomiting is less frequent than after either chloroform or ether. In dispensary practice the child begins to cry after a few breaths, a slight shake rouses it completely, the mother picks it up and by the time it is dressed the mother can take it home.

An interesting and typical case which I saw at the Good Samaritan Dispensary, New York, a few days ago was that of a middle-aged woman who had been anesthetized for about five minutes while an ugly mammary abscess was opened, cleaned and packed. She lay still for about a minute after the mask was removed, and then taking several long breaths opened her eyes and was helped to sit up on the table. She looked about her in a puzzled sort of a way, then slid down from the table without any assistance, arranged her clothing and after a few minutes walked around to the surgeon showing and asking relief for the eroded nipple of the other breast. A similar course marked the completion of a minor operation at the Norwegian Hospital (Brooklyn) a short time ago. A few moments after the operation the patient was out in the corridor drinking a glass of water.

This freedom from annoying after-effects is seen in most cases, but there are some patients who vomit. This seems to be a misadventure from which no anesthetic is entirely free. However, the vomiting is neither severe nor of long duration. Some observers have never seen it. In a personal communication from the Massachusetts General Hospital, Allen says he sees nausea and vomiting in many cases: Rose (Bristol) says in two per cent., Bossart (Aaran) twelve per cent, Cumston[21] (Boston) twenty per cent., Girard (Toulon) thirty-nine per cent. McCardie says it occurs more often with ethyl chloride than after nitrous oxide, less frequently than after the so-called "heavy" anesthetic agents. The amount of the anesthetic used is doubtless a determining factor.

This is also true of any effect upon the liver and kidneys. Gaudiani[2] found albumin after a long operation; Nouvé-Josserand[7] only when much ethyl chloride had been used. Reboul[9] did not find any albumin at all. Dumont[11] says König did not find any. Girard[20] and Malherbe found both albumin and bile pigment. Seitz did not observe any adverse changes even in a patient with an amyloid kidney. Another author makes the sweeping assertion that neither dyspeptics, nor hepatitics, nor nephritics, are in any way injured by ethyl chloride.

The skin does not give many signs. Cyanosis is exceedingly rare, even with a "close" method, and depends entirely upon mechanical causes. There is no pallor; on the contrary the tendency is to a dilation of the superficial capillaries of the face and the upper trunk so that a slight erythema is sometimes noticed or even a pronounced rash. A warm moisture is frequently observed both during and after the anesthesia. This external vascular movement has led Girard[20] to assume a similar determination of the blood to the brain and medulla. If this assumption can be established it will give rise to a comforting optimism that the vital centers are in no danger from anemia.

But the effect of ethyl chloride upon the vital centers and brain is not yet unequivocally determined. However, a particular observation which is especially emphasized, is its evident and pronouncedly selective action upon the dissociating brain neuroglia—hence the early incoordination of both movement and perception. If now, according to Schleich's theory[22] of the varying degrees of resistance to any anesthetic of the several cortical layers, in accordance with which it is supposed that the nerve cells are least affected in the lower cerebral planes, and that the purely vegetative or automatic functions are governed by the lowest strata of the brain substance, then one would feel like believing that because ethyl chloride acts so rapidly upon the upper portions it does not need to be pushed so far as to deeply affect the older and more resistant areas of the purely organic functions of the brain. Besides this, the motor ganglia of the cord seem to be peculiarly resistant or may be even stimulated so that a more or less continued tonic spasm of the voluntary muscles is present to some degree all through the course of an operation.

In noting his observations of the effect of ethyl chloride upon the heart Nové-Josserand is inclined to believe that some heart depression which was manifested was due to vagal stimulation, for this, he says, ceased upon section of the vagus. Girard, on the other hand, after numerous experiments, is very emphatic in his opinion that the "moderator center is really inhibited" as it were, and adds: "We insist upon this important fact—a fact the value of which experience has proven—that a secondary cardiac syncope ought not to be feared in the course of an established anesthesia." Since Girard also denies any irritation of the trigeminus, it will be seen that he also does not fear any reflex heart failure in the beginning of the anesthesia. Seitz, however, having seen some unpleasant interferences with the respiratory rhythm is afraid that the sensory fibers of the trigeminus might be irritated enough to cause a glottic spasm, and that if there were any impairment of the coronary arteries, the resulting increase of the intrathoracic pressure might close them and cause death. He is the only one, by the way, who expresses this fear, and even then he limits his objections to the use of Kelene. Henning's preparation he finds to be much less pungent and irritating. I must say that I cannot

smell any difference; to me neither is in the least degree unpleasant.

So ethyl chloride may be dangerous. To be sure, it is only relatively safe. And yet, according to present statistics it is the least dangerous of all anesthetics, excepting only nitrous oxide. Most of the half dozen deaths which are reported have been unjustly charged against it. Lotheissen[23] (Innsbruck) has looked into all the records and has this to say: "The anesthetic in Soulier's case was not ethyl chloride (C_2H_5Cl) at all, but ethyliden chloride ($C_2H_4Cl_2$). Zeitz' (Zürich) death occurred sixteen hours after local use. In another instance ether for forty-nine minutes followed a one minute exhibition of ethyl chloride. McCardie's (Birmingham) case was that of a very debilitated patient who died an hour and a quarter after regaining consciousness. The autopsy showed nephritis, chronic adhesive peritonitis, pleuritis, and a fatty liver. Surely a bad case for any anesthetic. Bossart's case also was contraindicated for general anesthesia. A tracheotomy was to be done upon a cyanosed child to relieve the dyspnea caused by laryngeal diphtheria. Lotheissen's own case in 1901 was an alcoholic, forty-one years of age, who died within three minutes after the anesthetic was begun and after only about 5 c.c. had been sprayed into the Brewer mask. The case has been widely discussed. The necropsy revealed fatty degeneration of the heart and marked coronal sclerosis.

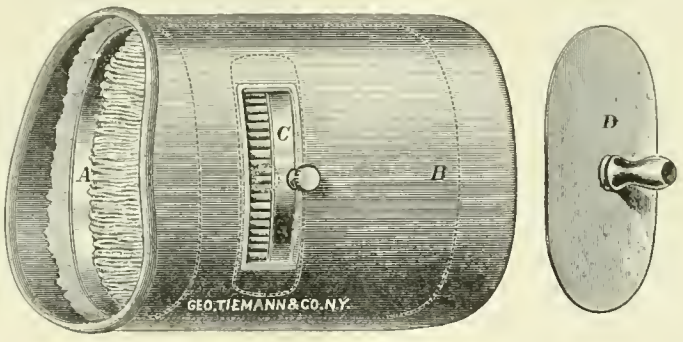
The December, 1903, *American Journal of the Medical Sciences* reports a death at the University of Pennsylvania Hospital. The man did not die from the effect of the anesthetic. He vomited an enormous quantity of an almost clear watery liquid for about three minutes without any retching or inspiratory effort. When vomiting finally stopped he was dead. Lotheissen's death was probably due to an initial irritation of the trigeminal fibers, and in McCardie's case the anesthetic, if not the sole cause, was yet a factor. Since at least 25,000 anesthesias have been given—30,000 is more likely—this surely is not a disquieting statistic. Some dangerous minor symptoms have been reported. But these were clearly due to an accidental overdose (Bossart's case) or "the outcome of neglected attention to a retroplaced tongue, or a disregard of sufficient admixture of air" (Ware's[24] cases).

And now, in closing, a few cautions, a consideration of suggested contraindications and a recapitulation of the course of the narcosis.

The ethyl chloride must be chemically pure. The mask must fit the face snugly. As little as possible should be given—a half a dram is a good initial mass dose. Mauretta[25] gave up to three and four drams without ill effect, but the general opinion is against such practice. A graduated container must be employed, else the dosage is uncertain. Other rules every anesthetist knows: to watch the eyes, respiration and pulse; to insist upon quiet in and about the anesthetizing room, and to avoid an open flame.[21]

Only two contraindications have been suggested. If the laryngeal aperture is abnormally small, lest it be aggravated to a stenosis by an irritating vapor. If any kidney disease is present. But Girard alone suggests this danger. It is not commonly held that the kidney suffers any harm.

Ethyl chloride is a safe, pleasant, rapid systemic anesthetic agent. The preanesthetic or short analgesic stage continues for only a fraction of a minute, and is followed by a condition



characterized by some tonic contractures, accelerated respiration and usually a moderate degree of mydriasis; this is called the catalyptic stage by some, the stage of contracture, or the stage of analgesia by others, and is suitable for short operations. After two to five c.c. have been inhaled, or more, in the case of large adults, usually after fifteen to sixty seconds, or sooner in children, the third stage that of profound anesthesia supervenes. The muscles are now relaxed, the breathing is deep and rhythmical, perhaps snoring, usually the pupil continues to be somewhat dilated, and the conjunctival reflex is abolished. In some instances the patient passes at once into the third stage, sometimes it takes five minutes, once in a while the third stage is not reached at all. If the ethyl chloride is to be continued small doses, say one c.c., are given about every minute; or if a mixed anesthesia is to be used the change can readily be made if the modified Allis inhaler is employed. The patient is awake within a few minutes after the mask is removed. After a short anesthesia he is seldom nauseated and rarely complains of a headache. He may be a trifle upset by his strange position and surroundings, but he will quickly recover himself. If it

was a long operation and he is taken to the ward he soon will be as natural as the other patients. If it was a short operation, say in the office, he will not be delayed long from going about his business.

To one desirous of considering this subject in greater detail, the author commends Ware's several papers, McCardie's excellent article, Cunniston's comprehensive essay, Girard's detailed description, and the chapters on ethyl chloride in both Dumont's and Zeitz's excellent books on anesthesia.

MEDICAL PROGRESS.

SURGERY.

Traumatic Asphyxia.—The number of these cases which have been studied in life is very small, six cases in all having been reported. H. H. A. BEACH and FARRAR COBB (Ann. of Surg., April, 1904) report a case which is of particular interest because it is accompanied by a close description of the pathology of the skin which clears up all doubt as to the nature of the lesion and cause of the discoloration. The patient was a robust German, thirty years of age, who had been caught an hour before entrance to the Massachusetts General Hospital in a moving freight elevator. He was held from three to five minutes. While being released, his face became black, blood poured from his nose and mouth and his eyes protruded. He became unconscious. Physical examination showed that he had been severely injured from the buttocks to the midthoracic region. In the left loin was a large fluctuating hematoma, the eighth and ninth ribs on the left side were broken. Heart and lungs were negative. The face was of a purplish hue, this color extending from forehead to just above the clavicle. Pressure on this black skin did not cause it to pale. What is characteristic of all cases was noted here, viz., at the back of the neck there was none of the discoloration except within the confines of the trapezius. There were no retinal hemorrhages. The subconjunctival hemorrhages were so excessive as to cause that membrane to bulge. The pupils and urine were normal. Patient recovered without complication save for an acute involvement of his lungs lasting over twenty-four hours. Forty-eight hours after the injury bits of skin were removed from the neck and subjected to microscopical examination. Seventy-two hours after the injury the discoloration disappeared very rapidly by simply fading out. The discoloration did not undergo the usual chemotactic changes seen in the absorption of a blood clot. The cause of this unusual condition is generally admitted to be forcible compression of the chest lasting over several minutes and accompanied by cessation of respiration. Death of individuals in struggling crowds and mobs has often been accompanied by this symptom. There are no gross post-mortem findings in these cases other than those usually characteristic of cases of suffocation. Wright, pathologist of the hospital, reported that every section studied showed normal skin, nowhere were evidences of blood in the tissues outside of the blood vessels. This, combined with the absence of chronic change, appears to the authors to show that conclusions to the effect that hemorrhages are the cause of the discoloration are erroneous. As to the cause of the sharp limitations of the color to the head and neck, the writers make no suggestions, but are inclined to consider favorably the theory of Perthes which ascribes it to the lack of valves in the jugular and facial veins. The conclusions are that the immediate use of artificial respiration in these cases is the only therapy indicated. The development of what has been called contusion pneumonia is very common and yet it should be remembered that so far as the literature goes, this may be depended upon to clear away without serious trouble.

Appendicitis in Children.—The diagnosis of appendicitis in children is usually more difficult than in adults from the fact that one must rely largely upon objective signs and such symptoms as are obtainable from parents and nurses. J. F. ERDMANN (N. Y. Med. Jour., March 19, 1904) has seen 29 cases in children under ten years of age during the past two years and reminds the profession that the most important diagnostic points to be relied upon are pain manifested by fitful crying and sleep, abdominal tenderness and rigidity of the right lower quadrant after the first few hours have elapsed; the absence of blood and bloody mucus in the stools, elevation of the pulse and temperature, usually more pronounced in children than in adults; tumor fixed and in the classical position if the illness is of several days' duration, and at this time a temperature characteristic of pus. Almost invariably the little patients unconsciously place their hand in the region of the appendix to ward off manipulations in this area. This latter sign he thinks is almost pathognomonic of appendicitis. Pneumonia and pleurisy of the type that is ushered in with lower intercostal pain is exceptionally difficult to exclude during the first day unless distinct chest symptoms are present. Should the pulse become very rapid and the face become anxious, appendicitis can be diagnosticated, while, if the breathing becomes accelerated, the face flushed or livid, although the abdomen be tense and distended, pneumonia is to be considered. He believes that when appendicitis is once diagnosed the patient is always in danger till the organ has been removed and hence he advises an operation in all such cases.

Wound Infection from Speaking at Operations.—The idea that infection of an operative wound may take place from the air expired by the operator has been practically abandoned. The possibility that infection may result from the minute particles of saliva which are extruded by most persons during speech, has led MENDES DE LEON (Archiv f. klin. Chir., Vol. 72, No. 4) to make some experimental observations. In a special sterilized receptacle, provided with an opening into which the operator could speak, were placed the agar plates. The culture results from a large number of trials convinced the author that during the course of an operation, a very large quantity of staphylo-, strepto- and diplococci were expelled from the mouth during the act

of speaking and so came into contact with the wound. This danger can be obviated, according to the author in two ways: Either by chemical or mechanical means. The first includes cleansing of the mouth by antiseptic solutions; the second, some means by which the germs may be caught up and rendered ineffective. The former method was found by actual experiment to be ineffective. A most efficient mechanical device was constructed, however, which consists of a double perforated metallic mask which can be closely fitted over the mouth. The space between the two perforated sheets is filled with sterile cotton and the entire apparatus may be readily sterilized. It is fastened by tapes and springs back of the ears. Repeated trials showed that the maximum number of colonies which developed on agar plates was five.

Pathology and Surgery of the Pancreas.—Virgil observed, "Drops wear away the stones, not by force but by constantly falling." The crystallized opinions of the medical profession are more difficult to wear away than the hardest trap rock. But if continual appeal will have any effect, the time will certainly come when a more liberal attitude toward surgery will be held by the average practitioner. A. W. Mayo Robson (Lancet, April 2, 1904), in concluding the third of the series of lectures on the pancreas, states that it is his fervent hope that the labor of his life, which has largely been devoted to the pathology and treatment of this organ, shall not be in vain. The symptoms produced by a pancreatic cyst are dependent on the nature of the disease producing cyst formation and secondarily and much later to the pressure exercised by the tumor. Fatty stools, azoturia, pale, bulky motions and glycosuria will be present or absent according to the amount of degeneration in the gland. It must not be forgotten that there have been numerous cases of pancreatic cysts which presented very few symptoms save the presence of the tumor. Surgeons are universally agreed as to the wisdom of draining pancreatic cysts, but occasionally the question may arise whether or not extirpation is not to be preferred. Tapping and aspiration are looked upon by the author as antiquated and ineffective methods, which are attended with more danger than the operation of incision and drainage. Von Mikulicz has so ably dealt with the injuries of the pancreas that little remains to be said. If, after an injury, however trivial, in the superior abdominal region, there be increasing anemia or evidences of peritonitis, immediate operation is indicated. As to calculus formation, it is probable that it never takes place in a healthy pancreas; like gall-stones, pancreatic contusions are the result of catarrh of the ducts, the stagnation of secretion, which generally, if not always, results from infection. The author suggests for this lesion the term "Pancrealithic catarrh." The calculi are very apt to be multiple and it will be invariably seen that the glands have undergone serious degenerative changes. The composition of the pancreatic calculi is important from a diagnostic viewpoint. It is well known that normal pancreatic secretion contains no calcium carbonate. In jaundiced cases the bile acids take up the lime salts to such an extent that oxalate of lime crystals have been found in only six per cent. of these cases. The very important result of this is that one is enabled to see them by the X-ray, thus differentiating them from gall-stones and diagnosing their presence. Medical treatment for these calculi is useless here as elsewhere. The typical picture of malignant disease of the pancreas may, in the author's words, be thus drawn: "A patient suffers for a time from indefinite symptoms of digestive disturbance, then jaundice appears, coming gradually but persistently increasing; the gall-bladder is usually distended and the liver is normal or slightly enlarged. A tumor may be found in the neighborhood of the pancreas. Cachexia rapidly develops and in some cases pain disturbs the patient's rest. There is soon a feeling of intense prostration and weakness. The feces are massive and contain fat or fat-acids and an undue proportion of undigested muscle fiber. The urine contains albumin frequently and sugar and fat rarely. The whole clinical course is run, as a rule, within twelve months and, after the appearance of jaundice, within from six to eight months."

Perineal Litholapaxy.—This operation, which was originally described by Keith in 1892, has not met with the success which its advantages should justify. Litholapaxy in children is always a somewhat anxious undertaking. A. Hooton (Brit. Med. Jour., April 9, 1904) states that many authors indicate the performance of the perineal operation under some or all of the following conditions: (1) A large stone necessitating the use of a lithotrite which will not pass easily by the natural route. (2) A very hard stone necessitating the passage of a similar instrument. (3) Stricture in conjunction with a large or hard stone or perhaps of any stone. (4) A difficult or narrow urethra. (5) Imperfect equipment. (6) Cases in which litholapaxy has been commenced in the ordinary way but cannot be completed satisfactorily owing to swelling of urethra and deposit of débris. The operation differs somewhat from that of lithotomy. A curved staff with a median groove is introducted into the bladder. The scrotum is allowed to assume its natural position. A very small incision is now made with the point of a tenotomy knife, in children about one inch in front of the anus through the median raphe and the urethra, incised for one-eighth of an inch. The point of an ordinary director is inserted through the wound and passed into the bladder, which is then dilated up to the required size. The evacuating catheter is now passed, the bladder injected and the lithotrite follows without difficulty. The operation is completed in the same way as in ordinary litholapaxy, and, as a rule, there is no difficulty in retaining fluid in the bladder. In order to avoid a valvular aperture, it is most important that the skin should not be displaced while making the incision, but should be left to hang in its normal condition. This method has never been intended to replace lithotomy, which will always remain the operation of choice.

Bone Suture with Silver Wire.—The objections to the use of this material have always been centered in the possibility of postoperative infection. It seems as though the two places in the body where non-absorbable suture material could favorably be employed are the intestines and the bone. The fear, however, has always been in the case of the latter, that great difficulty and annoyance would be experienced in removing the suture should infection occur. This has led to a rather wide use of catgut, which has been chromicized for a sufficient length of time to enable it to resist absorption almost indefinitely. While there can be no absolute necessity for inserting a metallic body in a joint which ultimately is going to heal to be stronger than any other portion of the bone, like the joint of a plumber's pipe, yet it is confessedly advantageous during the first few months of healing to have some strong fabric discounting the differential muscle traction. H. Grisson (Zntrlbl. f. Chir., March 19, 1904) presents a very clever method for tying silver wire, which has been used to maintain the juxtaposition of broken bone, and which cannot fail to give great delight to those who feel that wire is indispensable for the treatment of these conditions. The technic is simply to tie two knots in the course of the wire at a sufficient distance apart so

that when one is against the bone, the other will lie beyond the soft parts. The suture is then carried in the usual manner through one bone from above downward and from below upward through the other. The needle end is then cast about the proximal knot, which is slightly raised from the bone. It is then pulled through with a pair of forceps and left in the form of a loop, the loose extremity hanging out of the wound. This clever form of knot cannot possibly untie. The more tension placed upon it the tighter does it become. Should suppuration occur, the technic of removal is very simple. One simply draws upon the unknotted end, which has been carried alongside of the knotted end well out beyond the skin wound, until the loop is felt to be released. Gentle traction on the knotted end will without difficulty remove the entire suture without injury to the soft parts.

THERAPEUTICS.

Prophylaxis of Gonorrheal Ophthalmia.—Since Credé has introduced his valuable silver nitrate instillations, gonorrheal ophthalmia has almost disappeared from institutions but is still common in private practice, since midwives do not generally practise the method. The original instructions are still followed except that a one per cent. solution is generally employed, as irritation is less liable to follow. D. DAUBER (Münch. med. Woch., Feb. 16, 1904) states that many attempts have been made to substitute some less irritating silver salt for the nitrate. Protargol in 20 per cent. solution and silver acetate in one per cent. solution have been tried extensively, but the results are not much better than with the nitrate. Even where the silver acetate was followed by sodium chloride the percentage of silver-catarrh was greater than with the nitrate. As the cases of blindness secondary to puerperal gonorrhea are still very numerous, it is absolutely essential to instruct midwives in the proper care of the eyes after birth.

Olive Oil in Diseases of the Stomach.—Since the operative treatment of pyloric stenosis has on the whole been unsatisfactory—some of the best surgeons still report 16 per cent. mortality after gastro-enterostomy—every new internal method demands a careful trial. P. COHNHEIM (Zeitsch. f. klin. Med., Vol. 52, Nos. 1 and 2) has seen excellent results from large doses of olive oil; in spastic stenoses an absolute cure will follow, while in cicatricial stenoses more relief is obtained than after any other method, provided complete atresia does not exist. Good effects are even seen in pyloric cancer for the oil easily passes the narrow opening and acts as food. It is best to wash out the stomach in the morning and then to introduce 100 to 150 c.cm. of the warmed oil; after this patient lies down on right side—and fasts for an hour. If the patient does not completely lose his pains during the day, he is instructed to take 50 c.cm. before retiring. Later in the treatment the patient also takes the morning dose himself; a wineglassful one hour before breakfast and one to two tablespoonfuls one or two hours before dinner and supper will then suffice. In mild cases an emulsion of almonds may be substituted for the last two doses. In purely hysterical spasm relief is not generally seen, so that the oil may be occasionally employed to decide the diagnosis. After-effects, such as eructations and diarrhea are rare and only few complain of the taste. It will often be possible to avoid an operation with doubtful outcome, if the oil cure is employed systematically.

New Laxative—Purgatin.—Ebstein reported some two years ago his favorable observations on purgatin as a laxative devoid of any of those unpleasant results, such as abdominal pain, nausea, tenesmus, etc., that are so characteristic of this class of drugs. To determine the real nature of the drug STRELKOFF (Roussky Vrach, No. 9, 1904) administered it to some 26 patients suffering from various diseases of the gastro-intestinal tract. His conclusions are as follows: (1) The drug does possess laxative properties, but rather to an inconsiderable degree; (2) it is tasteless; (3) it does not liquefy the feces. These few advantages are more than counterbalanced by the fact that the drug is apt to cause pain on urination, tenesmus, severe abdominal pains prior to evacuation of the bowels, tenesmus and pain during evacuation, nausea, borborygmus, diarrhea, etc. As small doses fail to cause the desired effect, repeated administration of the drug must be resorted to and this is apt to cause the above unpleasant symptoms. A purgatin habit is quickly established and patients require larger and larger doses. In short, without enumerating the other disadvantages presented by the author, it may be safely asserted that the drug forms no valuable addition to our arsenal of vegetable laxatives.

Practical Method of Destroying Snake Venom.—It is remarkable how broadening an influence upon the relatively small field of medical work, the acquisition of our colonial territories has had. L. ROGERS (Lancet, Feb. 6, 1904) describes a practical method of treating any kind of snake poison which promises to be of great value in all cases seen early. It is so simple that any intelligent person can carry it out. Calmette's serum is not strong enough to counteract full doses of colubrine venoms. Furthermore, it is seldom at hand when wanted and also, unfortunately, it tends to lose its strength in a hot climate. It is useless for viper bites. It becomes obvious that in a country which is infested by snakes of different species, many of whose bite means death, it is impossible to carry around with one a sufficient number of vials containing antitoxin for each snake. Again, it is not always possible for the victim to be certain of the species of snake which has bitten him. A method which shall destroy the poison locally at the seat of its injection is therefore more practical than that which deals with it after its entry into the circulation. Permanganate of potassium, as shown by Blyth, is the best known of these substances. Brunton, who injected strong solutions of this substance at the seat of the insertion of the poison, was unable to prevent death by this means. He and Fayrer, however, have recently suggested a more radical method of using permanganate. They advise ligation above the inoculation, then incision of the wound followed by the rubbing of pure crystals of the salt. The author has endeavored to discover whether the permanganate will destroy the venom of other snakes than the cobra. Ten to twenty times the lethal dose of poison mixed with very small fraction of permanganate gave positive protective results. It is positively established that the salt will destroy *in vitro* nearly its own weight in every class of snake venom. It is possible that the free pouring out of lymph in the neighborhood of the wound will sufficiently retard the absorption of the venom so that a half hour or more time may elapse from the infliction of the bite to the rubbing in of the permanganate. If a very large dose, say fifty times the lethal amount, is injected subcutaneously into a dog's tail, and this member is cut off proximal to the seat of injection within a few seconds, the animal will still die. The reason for this is that one fatal dose may be absorbed out of such a large quantity almost instantaneously. At the suggestion of Sir Lauder Brunton, a lance has been made surrounded by a sheath in the base of which permanganate crystals are kept, the whole outfit being easily carried in the corner of the vest pocket.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MAY 28, 1904.

BABIES AND HOT WEATHER.

The Health Department of the City of Rochester, N. Y., has issued a little circular, entitled "How to take care of babies during hot weather," which is evidently meant for distribution in crowded districts of the town. It is such an excellent compilation that we feel we should call attention to it, since other boards of health throughout the country may wish to imitate Rochester's provident example, and they will find in this pamphlet much that is suggestive, nothing that is not eminently practical.

The outside cover bears the legend "no other food, not even a wet-nurse, can take the place of milk from the child's own mother." In these modern days when a trivial excuse is sometimes considered quite enough to justify the weaning of the baby and when even physicians do not seem to be sufficiently impressed with the fact that nothing can ever make up entirely for mother's milk, it is well that this item of our present-day conclusions in medicine should be brought prominently before the public for its serious consideration.

Another excellent feature is found at the foot of the outside cover. In large capitals are the words "Give the Baby Water." There was a time not so long since, when babies practically never received simple, plain water. To-day it is a difficult matter to persuade some mothers that children should be given water several times a day. There are families, fortunately rarely met with in this country, in which when the child cries for a drink in hot weather it must take a full meal of milk in order to obtain the drink. Streaming with perspiration, the little one is taken up from its warm bed in the summer-time, crying because it is thirsty, and instead of being given water is given milk or the breast. Somehow the custom, common enough three generations ago, of providing water for baby, has gone out, except where the modern teaching of the necessity of water has been especially insisted on.

Not a few of the babies who suffer from constipation do so mainly because of the fact that not enough liquid is supplied to them to make their food sufficiently dilute so that peristalsis shall have a fair chance to move it easily. This did not mean so much when houses were warmed by fireplaces, as there was a constant draught of air from outdoors carrying a steady amount of moisture with it. Now, in steam-heated houses the necessity for water, even in winter-time, for children, is easy to understand, and in summer-time it is little less than the worst form of cruelty to deny it to them.

With such good points on the care of children on the outside of the little pamphlet it is not surprising to find that the inside is full of excellent suggestions. To keep a baby well, is the first paragraph and it consists of these short sentences: "Give it pure air day and night; give it no food but mother's milk, or that directed by physicians; when it cries or is fretful do not offer it food, but give it water; be sure that it gets enough sleep, two naps during the day at least; do not put too much clothing on it; bathe it in a tub every day; don't handle it. Let it alone." These are expanded in successive paragraphs. The necessity for having a window open in the baby's sleeping room at night and during the day, is insisted on. Then, also, the danger of overnursing or overfeeding and the necessity of stopping food soon as the first symptoms of diarrhea present themselves is urged. Regular feeding is emphasized and in capitals the expression, "*Feed it by the clock*," ought to attract sufficient attention to make readers realize its importance. Finally feeding according to age is made a feature. The chapter closes in this wise, "Never let the bottle stand with milk in it. Never use a bottle with a long rubber tube."

To our mind the most important paragraph in the book is that with regard to baby's sleep. The question of the proper sort of bed is discussed, and the use of feathers, in any form, whether in pillow or in the mattress, is rejected as entirely out of place, especially in summer. Wool or cotton must, for the same reason, be considered unsuitable. The very practical suggestion is made that babies' beds should be made of excelsior covered with cheese cloth. These materials are cheap and easy to obtain and when the mattress becomes soiled in any way, it may be thrown away and another one made without delay or cost. It is easy to understand that such a bed is at once clean and comfortable. The Rochester Board of Health, of course, is considering city life, but in country places such a mattress might be filled with corn husks or other suitable material, easy to be obtained on farms. The objection that will occur in most mothers' minds at once is that this is entirely too rough for baby and will injure its delicate skin. As a matter of fact, baby's skin will be much healthier with the opportunity for transpiration and perspiration afforded by such a mattress than by anything that presses close to its body and prevents the proper functions of the skin during the many hours that baby must pass in bed.

Letting the baby alone is recommended as the best possible way to prevent its suffering from the heat, more than is absolutely inevitable. When baby is ill, the place for it is not in mother's nor nurse's arms, but in its bed. Just because it happens to be fretful is no reason at all why it should be petted and jostled by being carried. When it is well it should be allowed to lie in bed so much as possible without much clothing on, so as to enable it to exercise its limbs freely. It is surprising how early in a baby's life it learns to play, if left to its own devices. When it is to be put to sleep, if put in its bed, it will go to sleep as a rule without rocking after a short preliminary cry. Crying is not a signal for it to be made still more uncomfortable in hot weather, by being carried in nurse's arms. Crying is, as the Board of Health points out, only one form of exercise of the lungs in children and when they are a little older they will make themselves a nuisance by still further exercising this function, but it should not be considered as something that must be stopped at all hazards.

While there are many suggestions herein that might not meet with the approval of mothers of large families, the advice is simple and practical.

PATIENT—PHYSICIAN—PHARMACIST.

In our Correspondence columns this week (p. 1040) we publish an important contribution that is of vital interest to every physician in the State of New York, if not in the United States.

By the ruling of Judge Gaynor, herein cited, two principles are laid down as good law. In the first place the competency of the medical practitioner as an expert in the knowledge of the action of drugs is considered secondary to that of a drug clerk, and secondly, an apothecary can, whenever he sees fit, substitute in a physician's prescription something "just as good" and receive legal sanction, if not approval—from Justice Gaynor at least.

The evils of substitution are too well known and recognized by all of us to need much further comment; yet, in the present instance, we find a drug clerk substitutes morphine and heroin for heroin alone, and yet this does not seem to strike the judicial mind as anything to be condemned.

The larger evil, however, resides, we believe, in the acceptance of the testimony of a druggist as relevant and as competent as to what constitutes a poisonous dose for a particular patient and the rejection of the testimony of the attending physician on the same issue.

We have never heard of an instance in which the testimony of a druggist, and an interested party in addition, who does not know the patient nor the nature of the illness, has been considered more relevant by a court of law than that of the family physician who by education, training, and special knowledge, is entitled to speak with authority concerning the case in hand. In the present issue such is the attitude taken by the learned judge.

Shall the courts uphold a violation of the legal relations which exist between the physician, the pharmacist, and the patient? If so, the physician must retire and leave the patient to the authority of the drug clerk, which Justice Gaynor holds higher than that of the practitioner of medicine.

Such a condition is intolerable.

ACUTE OSTEOMYELITIS.

This important affection has at last attained its proper place in nosology. It is still occasionally mistaken for acute articular rheumatism, especially in children, and this, too, at a time when delay is dangerous but ever more and more, in recent years, physicians and surgeons are successfully on their guard against such erroneous diagnoses. An element of difficulty in early recog-

nition of the disease is that no hint of the fact that the preceding affection to which it is secondary is about to affect the bone-marrow is ever given. It may occur after the simplest forms of infection. After a whitlow that runs a mild course, after a boil or furuncle that is no severer than hundreds of others that have been under observation without any sequela, or it may even be subsequent to an attack of typhoid fever that took place months, or even years before. As delay may be very dangerous, it is easy to realize how much this feature of lack of premonition may mean and how important it is not to disregard the slightest sign.

The most important form of the disease is acute infectious osteomyelitis, which is treated of very completely by Edward H. Nichols, in the *Journal of the American Medical Association* of February 13, 1904. To those who are unfamiliar with recent investigations into the etiology of acute osteomyelitis, it will be somewhat of a surprise to learn that the affection is usually due to the staphylococcus. The *Staphylococcus pyogenes aureus,* is more often present in pure cultures than either *albus* or *citreus,* though the *aureus* perhaps produces, at least according to the experience of French writers, more serious lesions. Staphylococci are usually not looked upon as very malignant organisms and are, when compared to the streptococcus, considered not to be especially destructive. In the bone-marrow, however, these properties of the two forms of microorganism are reversed. The *Streptococcus pyogenes* seldom produces such severe lesions as the staphylococcus. It always has a tendency to remain more superficial than the other, and, as a consequence, not infrequently invades neighboring joints or causes separation of an epiphysis.

Acute osteomyelitis, due to staphylococcus, may follow a cutaneous furuncle. It has itself been designated picturesquely as "a furuncle of the bone-marrow," and this is thoroughly descriptive of the pathological condition which is present. A peculiar form of the disease, though running a course not unlike that produced by the staphylococcus, is due to an infection by the pneumococcus and occurs subsequent to a pneumonia or a severe pleurisy with effusion due to infection directly from the lung, or to an empyema.

With this knowledge of the etiology it is easy to understand the necessity for prompt operation. The toxins of the disease soon cause severe ravages in the body unless the focus of infection is promptly removed. It has sometimes been suggested that drainage of the abscess of the bones and of the soft parts above the bones is sufficient as a preliminary operation. As Dr. Nichols insists, however, the bone-marrow itself is infected and must be drained. In a very early stage of the disease, however, to make extensive removal of bone is not necessary, and much less advisable. All that is necessary is to give perfect drainage to the bone-marrow. At this stage even curettement may do more harm than good and the bone may recover and repair the defect without the formation of a sequestrum.

The best results can be obtained not by trying to accomplish complete removal of the focus of inflammation at the time of the first operation, but after the establishment of drainage and waiting for a couple of months to undertake a second operation for the removal of whatever necrosis may have taken place. Dr. Nichols believes that from his own experience it is better to remove the sequestrum and involucrum rather than the sequestrum alone. Wherever there is dense cortical bone, its power of repair is very slight or practically absent. To leave an extensive cavity in bone, surrounded by a wall of this dense, almost ivory-like, material, is to invite failure of the operation, as the unhealthy granulations lining the cavity have no proper tendency to close.

A complete removal of a portion of the shaft of the bone is often the best possible technic. The excision must be carried sufficiently far into the normal shaft to get well above the medullary canal wherever it is occluded by dense ivory bone. The limits of excision must reach into vascular bone-marrow, otherwise the results hoped for will either not be obtained at all, or will be obtained so slowly as to be very discouraging.

ECHOES AND NEWS.

NEW YORK.

Women's Hospital Cornerstone Laid.—The cornerstone of the new Women's Hospital, on One Hundred and Tenth street, near Amsterdam avenue, was laid Tuesday afternoon by President John E. Parsons. Archdeacon G. F. Nelson opened the exercises with prayer, and a large gathering of members and friends of the hospital was present.

Reception Hospital at Saranac Lake.—A Reception Hospital has been incorporated to maintain a hospital in North Elba, Saranac Lake Village, in the Adirondacks, to care for confirmed consumptives. This institution is intended to relieve a class of sufferers who are turned away everywhere and who cannot be taken at the Trudeau Sanitarium at Saranac Lake because their cases are too far advanced to promise any hope of cure and because they are ill enough to need nursing. Miss Mary R. Prescott is the leader in this charitable movement, and she

now maintains a reception cottage at Saranac Lake, where this class of consumptives get the best of care, food, nursing and medical attendance, the charge for which does not begin to cover the running expenses. Miss Prescott assumes the responsibility for the deficit and her work is much praised by Dr. Trudeau, who with Dr. Edward R. Baldwin, John Harding and Oliver Prescott, Jr., of Dartmouth, Mass., are the managers of the new hospital.

Dr. Cook, President of Police Surgeons.—At a meeting of the Board of Police Surgeons in Police Headquarters, Dr. Stephen E. Cook was elected President of the Board for the eighteenth time. Though it had been the custom of the Board to choose its own President, Commissioner Greene appointed Dr. Edward T. T. Marsh, the chief executive of the body. When Mr. McAdoo became Commissioner he said he would let the Board of Police Surgeons manage their own family affairs. Dr. Marsh will retire on a pension soon.

Report of New York Deaf and Dumb Asylum.—The annual report of the above institution shows that 464 pupils have been cared for during the past year. Of these 204 were congenitally imperfect, and 93 before the age of two years. The causes are set down as follows: Basilar meningitis, 36; brain fever, 34; scarlet fever, 30; measles, 18; the rest from indifferent causes of various kinds.

Odell Approves Bill for New York Reception Insane Hospital.—One of the surprises which came out of the legislative chamber last week was the approval by the Governor of Senator Foley's bill authorizing the City of New York to acquire a site and to lease it to the State for the establishment thereon of a reception hospital for the insane, and authorizing the State Commission in Lunacy to erect such a hospital. Gov. Odell had feared that the bill carried with it an appropriation of $300,000.

Spread of Fatal Spotted Fever.—Dr. Hermann M. Biggs, in charge of the Bacteriological Department, said Wednesday that there were 97 deaths from this disease last week. From various diseases there were 150 deaths in the week. Last year in the corresponding week there were 36 deaths from spotted fever. Spotted fever has steadily increased since March 1. Not since 1872 has there been such an outbreak. According to Dr. Biggs, the disease at present is almost always fatal. Until recently the disease was supposed to attack only children, but from the statistics of last week's deaths it was found that 33 cases were of people between five and fifteen, years, 23 over fifteen years, and the remainder under five years. The Department of Health, to aid in trying to fight the disease, has offered to place at the disposal of all hospitals and medical practitioners the service of its laboratories for the diagnosis of cases. The germ is known as meningococcus. Dr. Biggs said that in cases of spotted fever attending physicians should send specimens of the germ obtained from patients to the department for a bacteriological examination.

Diagnosis of Spotted Fever.—Owing to the prevalence in the city of epidemic cerebrospinal meningitis, the Department of Health offers to place at the disposal of hospitals and medical practitioners the service of its laboratories to aid in the diagnosis of this extremely fatal disease. The meningococcus (*Diplococcus intracellularis meningitidis* of Weichselbaum) is found in the cerebrospinal fluid of the majority of cases and usually also in the nasal secretion. The Department of Health will examine free of charge specimens of cerebrospinal fluid, as well as smears of, and cultures from, the nasal secretion. Such examination will in many instances assist in the early recognition of the disease and in determining the nature of obscure cases. Special outfits, consisting of a blood serum culture tube, a sterilized swab, and a glass slide for the smear, can be obtained at the Department of Health, Fifty-fifth street and Sixth avenue. After obtaining the specimens, they should be sent at once to the Department. Reports will be sent by telephone and mail. Specimens of cerebrospinal fluid can be readily obtained by lumbar puncture, a simple operation easily performed by the attending physician himself, or any surgeon. The operation, in addition to being an aid in diagnosis, is directly beneficial because of the relief of the intraspinal pressure.

Summer Health Corps.—Health Commissioner Darlington said last week that the Governor's veto of the bill for an increased bond issue might so curtail his arrangements for sending out the usual summer tenement house squad as to result in a five-per-cent. increase of the death rate.

"We cannot plan for our special summer work," said Dr. Darlington, "until we know how much money we shall have to carry it on with. Of course this cut in funds is likely to fall most heavily on other departments, but it may affect us as well. We hope it will not, but if it does it means five or six per cent. more on the death rate."

In June of every year a special squad of physicians is organized by the Board of Health to work among the tenement house population, particularly among the children. Last year 75 physicians put in two months and a half at this work. To show the necessity for this extra summer work, Dr. Darlington gives a few figures. For the seven years ending in 1872 the death rate among children under five years was 133 per thousand. This loss has been reduced to 56 per thousand in the last seven-year period. Much of this improvement is due to the rigid milk inspection and to other modern sanitary precautions. But the special corps of tenement house physicians, it is estimated, save annually 20,000 lives of children that would have died under the careless system of a generation ago.

Gift for Manhattan Eye and Ear Hospital.—A gift of $40,000, just pledged by Edward R. Thomas, son of the late Gen. Samuel Thomas, to the Manhattan Eye and Ear Hospital has saved the directors of that institution from the loss of $125,000 in conditional donations. The directors, although they had raised the rest of the amount, felt rather apprehensive about the $40,000 which was lacking, until Mr. Thomas came to the front with his donation. The latest gift by Mr. Thomas is given as a personal memorial to his father. The Thomas family last year gave $50,000 to the same hospital to endow a ward, to be known as the "Samuel Thomas Memorial Ward." The announcement of Mr. Thomas's gift was made on Tuesday last while a meeting of the Board was being held by Dr. Walter F. Chappell. The latter, while paying a professional visit to the home of Mr. Thomas, happened to mention the predicament the hospital directors were in, and Mr. Thomas then and there pledged himself to come to their relief. Steps will immediately be taken to purchase the land for a new building. A site has already been chosen within a block of the projected Rockefeller institute for research in East Fifty-ninth street.

New York Psychopathic Hospital.—New York is to have its psychopathic hospital, says *Charities*. Governor Odell is to be commended for withdrawing his proposed veto of Senator Foley's bill, authorizing the city of New York to acquire a site and lease it to the State for the establishment of a reception hospital for the insane, to be erected and maintained by the State for the preventive and curative treatment of patients from the metropolitan district. As the Governor in his annual message to the legislature of 1903, and on several

other occasions had expressed himself as in hearty accord with the plan of the State Commission in Lunacy to establish such a hospital, and as the bill had been signed by Mayor McClellan, it was felt that the favorable opportunity for action afforded by the agreement of the city and the State authorities should not be lost. The Governor seems to have feared that the expenditure authorized for the erection and equipment of the hospital would necessarily come from the appropriation for new buildings, repairs and improvements made by the legislature of 1904, which is all needed for the relief of the overcrowding now so unfortunately prevalent at all the State hospitals. As the project requires concerted action by many different city and State authorities it seems extremely unlikely that the actual work of construction will be begun this year. An idea of the red tape which will have to be unwound is indicated by a capitulation of the steps which, under the bill, will need to be taken: (1) The city, having decided to act under the bill, must select the site. (2) The site must be approved by the State Commission in Lunacy. (3) The site must be acquired by the city by purchase or by condemnation proceedings. (4) The city's title to the site must be approved by the Attorney-General. (5) The lease of the site by the city to the State must be approved by the Attorney-General. (6) The State architect must prepare plans and specifications. (7) The plans and specifications must be approved by the State Commission in Lunacy. (8) The plans and specifications must be approved by the Governor. (9) The specifications must be printed and advertised for bids for a considerable period. (10) The State must then erect the hospital out of any moneys appropriated for new buildings, repairs and improvements for the State hospitals.

This procedure is so complicated that it seems very important that a beginning should be made this year. Even so, the most sanguine can hardly expect to see any building operations actually under way before its close. Too great stress has been laid upon the cost of the proposed institution. Bear in mind that it promises to be, in the long run, a source of great financial saving to the State, for if it succeeds in checking the alarming increase of insanity by its preventive and curative treatment of incipient and acute cases, it will save the State an enormous outlay for buildings and maintenance. Remember that taking into consideration the wealth-producing value of an able-bodied and able-minded citizen and the cost of providing accommodation and care for an insane patient, every person discharged cured means an estimated saving or gain to the State of about $500 a year. Then it is possible to realize what an increase of cures will mean in the wealth, as well as in the health and happiness of the people of this State. The State of New York is to be congratulated upon being the first to sanction the adoption of the most scientific and humane methods of treating the victims of a disease which ranks only second to tuberculosis as the greatest scourge of modern civilization. The administration of Governor Odell will long be remembered for its enlightenment in making possible the initiation of a new era in the treatment of the insane in this country. The members of the Board of Estimate and Apportionment of New York City will do well to forward the movement made possible by Mayor McClellan's approval of the bill providing for cooperation between the city and the State, and carry into effect the city's share of the provisions of the law by taking immediate steps toward the acquisition of a site that shall be centrally located.

Manhattan Dermatological Society. — Regular monthly meeting held on Friday evening, May 6, 1904, at the residence of Dr. Edw. Pisko; Dr. I. P. Oberndorfer presiding.

The following cases were presented: By Dr. Oberndorfer, a woman aged fifty-four years, with a lesion on chin and adjacent part of neck. Began last July on chin and gradually spread to neck; the lesion is indurated; its outer border being extremely hard; the center shows numerous papillary excrescences; a somewhat similar indurated patch is seen near the clavicular insertion of the right sternocleidomastoid muscles; presented as a case of morphea; this diagnosis with some reservation. Dr. Pisko thought it resembled the early stage of skin epithelioma; he fails to see any characteristic signs of morphea. Dr. Abrahams suggested large doses of KI for diagnostic purposes; to him the diagnosis was not so clear; it certainly does not resemble morphea. Dr. Gottheil regards it as a localized scleroderma. Drs. Cocks and Sobel express no opinion. Dr. Weiss said the cartilaginous hardness, papillary growths favored diagnosis of malignant tumor; the patch near sternum was undoubtedly a sign of metastasis; he termed the growth carcinoma lenticulare.

Dr. A. Bleiman showed a boy of six years, who at the age of six weeks exhibited signs of infantile eczema; the eczematous patches spread all over the body and during the first 3½ years of life at no time was the skin ever perfectly clear; at the age of four years, child underwent an eight weeks' course of treatment at the New York Skin and Cancer Hospital and was discharged cured; one month later the process broke out again and since that time the skin never cleared; six months ago, when first observed, patient showed the typical shotty papules, buboes, indurated and infiltrated skin and eczematous condition, confined chiefly to extensor surfaces of upper and lower limbs; presented as a case of true prurigo; the classical picture of the condition being considerably modified, the result of treatment of interest was the patches of atrophy shown on extensor surfaces of lower arms and legs. Dr. Pisko said the case was one of prurigo (Hebra). Dr. Gottheil likewise called it prurigo; the eczematous element was considerably exaggerated in this case. Dr. E. L. Cocks said he saw the case when it was under treatment at the New York Skin and Cancer Hospital, the diagnosis then made being general infantile eczema; there was marked itching, secondary infection, superficial ulceration and consequent atrophy, as now presented in patient; judging by the subsequent history and present appearance he likewise inclines to call it a prurigo. Dr. Oberndorfer failed to see the typical prurigo papule nor the indurated skin of the lower limbs; he knew of chronic relapsing eczemas which resembled this case. Dr. Weiss said six months' treatment would tend to alter the original condition; if the classical signs of induration, localization papules and buboes were present then, he would not hesitate to call it prurigo. Dr. Sobel thought we had to deal with a chronic eczematous condition in a scrofulous child.

Dr. Pisko showed a case of lupus erythematosus, illustrating the beneficial results obtained by the use of local applications of pure trichlor. acetic acid. He also showed a light negress with verrucous-like lesion of chin; present about one year and not under treatment during that period; patient acknowledges infection and dates initial lesion back fourteen years; presented as a case of lues. Dr. Weiss would not make a diagnosis of lues on appearances only; he said lesion was not typical. Dr. Oberndorfer does not consider this type of lesion as uncommon.

Dr. L. Weiss presented a girl of thirteen years, showing an irregular granulating patch on right cheek, about 1½ inches square; this lesion was of one year's dura-

tion; other lesions on cheek of long standing (but now healed) are recognized by scar tissue. Presented as a case of scrofuloderma.

Dr. W. S. Gottheil presented a case of tuberculosis cutis: the face and neck showed involvement; old lesions on face healed with resulting scar; the latter extensive and deep, adherent to bone; the condition is present about six years; it began on the neck; another lesion is seen on the left lower leg. Treatment consisted of Finsen light exposures, giving three-quarter-hour sittings three times a week. Dr. Weiss, in comparing this case with his own, stated that multiple lesions of this kind (Gottheil's case) speak for lupus; where the loss of substance was superficial, he would use the term tuberculosis. Gottheil's case he termed lupus serpiginosus exulcerans.

Dr. Gottheil also showed a case of triple chancres of the lip in a female; roseola on body. He also showed the following photographs: (1) Acne cornea (microphotos of sections); (2) lupus vulgaris; (3) chancre of lip; (4) tuberculosis cutis; (5) dermatitis exfoliativa; (6) bromoderma tuberosum.

PHILADELPHIA.

Decrease in Contagious Diseases.—The new cases of contagious diseases for the past week were 166 less than during the preceding seven days. The principal reduction was in typhoid fever which fell from 295 to 182 cases. Smallpox dropped from 27 to 11 cases and scarlet fever from 100 to 65 cases.

Charters for Medical Institutions.—The People's Hospital of Frankford has applied for a charter. No site has been selected for the building. The White League, an association for the treatment of tuberculosis, has also made application for a charter. The object of the League is to treat tuberculosis by modern means and also to furnish employment for the patients.

Women's Medical College.—At the fifty-fourth annual commencement held recently a class of 43 was graduated. The alumnæ now number 1029. A bronze tablet erected in the gymnasium to the memory of Dr. Susan P. Stackhouse was unveiled with appropriate ceremonies.

Dr. Oliver a Guest of the British Medical Association.—Dr. Charles A. Oliver, of Philadelphia, Pa., has been chosen by the British Medical Association as its official guest from the United States for its seventy-second annual meeting, which is to take place in Oxford, England, in July. With him are associated Prof. Hirschberg, of Berlin, representing Germany, and Dr. Javal, of Paris, representing France. During his stay Dr. Oliver will reside at Keble College as the personal guest of Mr. Robert Walter Doyne, the President of the Ophthalmological Section of the Association and Lecturer on Ophthalmology at Oxford University.

Philadelphia Hospitals' Association.—The meeting of this association on May 16 received the report of a special committee condemning the milk supply of many of the hospitals of the city. As a result several of the institutions have made arrangements for the bacteriological or chemical test of their milk. At the same meeting Dr. Lawrence F. Flick made an argument in favor of the treatment of the tuberculous by the general hospitals. He finds that there is an average daily vacancy of 1,600 beds in the various institutions, this being about the number needed by the city for the proper care of its tuberculous. The hospitals should admit curable cases and the city provide their maintenance.

Witch Doctors to be Eradicated.—It is stated that the Berks County Medical Society and the State Medical Board contemplate a crusade against the witch doctors of Eastern Pennsylvania. These "voodoos" are patronized in Berks, Lehigh, Bucks, Lancaster, and Dauphin counties. Many charms have been collected as evidence against these crafty individuals who secure fat fees by putting aright the cases of "Hexerei" as they are known. The practice is based on a small book of charms and queer incantations as remedies written some eighty years ago by J. G. Hohman, a pioneer witch doctor of that region.

Jefferson Medical College.—A class of 169 was graduated at the seventy-ninth annual commencement held May 27. The degree of LL.D. was conferred on Prof. Dr. Albert Hoffa of the University of Berlin. Dr. Hoffa was the guest of honor at the alumni banquet held May 26, and on the same day gave an orthopedic clinic at the Jefferson Hospital. To perfect the faculty organization of the college the trustees have advanced to full professorship, with seats in the faculty, the following clinical professors: Ophthalmology, Dr. Howard F. Hansell; clinical surgery, Dr. W. Joseph Hearn; dermatology, Dr. Henry W. Stelwagon; orthopedic surgery, Dr. H. Augustus Wilson; diseases of children, Dr. Edwin E. Graham; genito-urinary surgery, Dr. Orville Horwitz; otology, Dr. S. MacCuen Smith; laryngology, Dr. D. Braden Kyle; clinical medicine, Dr. Solomon Solis-Cohen, and physiology and hygiene, Dr. Albert P. Brubaker. In addition to these changes, Dr. John H. Gibbon, surgeon at the Pennsylvania Hospital, was elected associate professor of surgery. Dr. Randle C. Rosenberger, assistant professor of bacteriology, and Dr. Aller G. Ellis, associate in pathology.

Prof. Munyon Must Pay $20,000.—In their suit to recover $50,000 damages from Munyon's Homeopathic Remedy Company, Rebecca E. and Peter B. Sprenkel received a verdict for $20,000 in the Court of Common Pleas. Mrs. Sprenkel, who was brought into court on a stretcher, declared that she was injured by the treatment given to her by Dr. W. S. Moat, one of Prof. Munyon's assistants. Physicians for the defendants swore that the treatment was the one prescribed by medical authorities.

Faculty Reorganization, University of Pennsylvania.—A plan for the reorganization of the Faculty has just been approved by the Board of Trustees, whereby the Faculty membership has been extended to the Clinical, Associated and Assistant Professors, to the Associates and Lecturers and to limited representation from the subordinate staff. The scheme provides for an executive body or Council, to be composed of the heads of the Departments in the fundamental subjects and two representatives of the Specialists. The plan will be put into effect September 1, 1904.

University's New Laboratories.—On Friday, June 10, with exercises commencing at 4 o'clock in the afternoon, the University of Pennsylvania will dedicate a new medical laboratory on the south side of Hamilton street, between Thirty-sixth and Thirty-seventh streets, on the site of the old Veterinary Hall and Hospital. The building is two stories in height above a high basement and measures 337 feet in front by nearly 200 feet in depth. The long front faces north, securing a maximum amount of the best light for laboratory purposes. In completeness of equipment this new building is without a rival. It provides for the teaching of students and the carrying on of research work on physiology, pathology and pharmacology, in which departments of medicine the greatest advances have been made in the past, and may be predicted for the future. The exercises comprise a procession of students, faculty, and guests from Houston Hall to the new building, where the following program will be carried out:

Presentation of building and opening of laboratories; presentation to the Trustees by J. Vaughan

Merrick, Esq.; acceptance on behalf of the Trustees by C. C. Harrison, LL.D., Provost of the University. Formal addresses in the Laboratory of Pathological History by Professor H. P. Bowditch, Professor of Physiology, Harvard University; Professor R. H. Chittenden, Director of the Sheffield Scientific School, Yale University; Professor George Dock, Professor of Medicine, University of Michigan; and Professor Horatio C. Wood, Professor of Therapeutics, Materia Medica and Pharmacy, University of Pennsylvania. The first floor of the new laboratories is to be devoted to physiology and pharmacodynamics. The department of physiology on the first floor will have provided one large room in which there will be ninety cabinets, fully equipped with such apparatus as is required in the practical exercises in physiology carried on by the students. The department of pharmacology has also been provided for on the first floor. This contains a large laboratory for practical pharmacodynamics; a large laboratory for practical pharmacy, a museum, a library and various rooms for the instructor and his assistants for research work, etc. The second floor will be devoted exclusively to pathology, with temporary accommodations for a number of the professors of other departments until the completion of future building operations rendering possible the final transfer of the entire medical school to buildings adjacent to the present new building. The entire north front of the building (with the exception of the temporarily arranged private rooms for various professors and the general pathological office) is devoted to laboratories for advanced students in experimental pathology and pathological bacteriology and the special research and assistant's rooms. There are two demonstration and two lecture rooms in the building. The two demonstration rooms each seat 185 students. These rooms communicate with two preparation rooms each. At the rear of the building there are two large lecture rooms, each seating 400 students. The architecture is distinctly "Pennsylvanian," and conforms to that of the dormitory system, the new law school building, gymnasium, engineering hall, and the stadium of the university. It may justly be regarded as one of the most impresisve buildings in Philadelphia.

CHICAGO.

Big Sum for New Hospital.—Over $400,000 has been raised by the committee of eight for the erection of a new Michael Reese Hospital, and at the joint annual meeting of the Board of Directors of the United Hebrew Charities and the Associated Jewish Charities, Leon Mandel, Edwin G. Foreman, W. N. Eisendrath, Moses Born, Julius Rosenwald, Maurice Rosenfeld, Moses E. Greenbaum, and Herman F. Hahn, were appointed a building committee with power to act.

Provide for Fourth of July Victims.—Dr. J. B. Murphy was recently elected Chairman of the committee organized by the promoters of Chicago's "sane" Fourth of July to care for children and others who may be injured that day.

Nurses Given Diplomas.—At the graduating exercises at the College of Physicians and Surgeons, held May 18, twelve nurses, who had completed the three years' course at the West Side Hospital, were given diplomas.

Farm Inspection.—Dr. John C. Cook read a paper on this subject before a recent meeting of the Chicago Pediatric Society. Among other things, he said that the first requisite to good milk is good cows, and it is the opinion of milk producers that the milk from a so-called "breeder's herd" is the more valuable to both producer and consumer. First, they are better cared for; second, the farmer is constantly trying to improve his herd by disposing of the poorer ones, and replacing them with better animals. The most practicable standard for the estimation of cleanliness in the care and handling of milk is its relative freedom from bacteria, and most commissions which have taken action in this matter have tentatively fixed upon the maximum of 30,000 germs of all kinds per cubic centimeter of milk, with a minimum of four per cent. of fats and all the other characteristics of pure, wholesome milk, in order to obtain the endorsement of the commission. Dealers who incur expense and take the precautions necessary to furnish a truly clean and wholesome milk should have some means of bringing these facts before the public. He pointed out the required conditions of the premises. The whole premises used for dairy purposes, as well as the barn, must have a supply of water free from any danger of pollution with animal matter and sufficiently abundant for all purposes, and easy of access. He emphasized the importance of the milker being personally clean, also the dairy utensils, saying that the latter should be thoroughly cleansed, first, by thoroughly washing with a brush and soap, then rinsing in warm water and sterilizing with steam.

GENERAL.

McGill University.—Dr. J. T. Halsey, lecturer in pharmacology at the university, whose resignation was recently accepted, has been appointed professor of therapeutics and clinical medicine in the Tulane Medical University, New Orleans. Dr. Skane, registrar of the McGill medical faculty has been recommended to the corporation to succeed Dr. Halsey.

Queen's University Alumni Dinner.—The second annual meeting of the alumni of the Medical Department of Queen's University, Canada, was held on May 18 at Muschenheim's. About 50 members were present, all of them in active practice in this city and in Brooklyn, some having graduated so long as forty years ago. The present New York association was organized two years ago by Principal Grant, late of Queen's, and has been growing in numbers ever since. President J. R. Shannon made the opening address setting forth the purposes of the organization and urging those present to invite any alumnus to join who by any possible chance did not know of its existence. This was followed by a speech from the Principal of the University, Rev. Dr. Gordon. Toasts were given for the King and for President Roosevelt.

The American Medical Temperance Association.—The thirteenth annual meeting of this association will be held in the parlors of the Hotel Dennis, at Atlantic City, June 8 and 9, 1904, at 9 A.M. A very interesting program has been prepared including an address on the effects of alcohol on the structures of the body, by the honorary president, Dr. N. S. Davis, of Chicago, and also a review of late researches concerning alcohol as a drug in medicine by Prof. W. S. Hall, the president. Other papers on allied topics will be read by Drs. MacNichol, Crothers, Mason, Kellogg, Reynolds, Steward, Reese, Paulison, Madden, and others. The object of this association is to encourage and promote the clinical, therapeutical, pharmacological, and chemical study of alcohol in health and disease. It also aims to gather, compile and make available the studies and experiences of medical men in all parts of the country, concerning the use of alcohol, and to formulate such definite facts as can be

utilized and made available in the practice of medicine. The spirit and purpose of the association is a purely scientific one, concerning the nature and the character of alcohol, irrespective of all possible conclusions. Regular practitioners of medicine may become members by a two-thirds vote of the association after signing an application to the secretary. All persons interested in this great topic are earnestly invited to attend the annual meeting. For particulars address T. D. Crothers, Secretary, Hartford, Conn.

Professor Charles S. Sherrington's Lecture on Cerebral Localization.—Prof. Chas. S. Sherrington, M.D., LL.D., F.R.S., of the University of Liverpool, gave a lecture on May 5, in the Medical Hall of the University of Pennsylvania, on "Cerebral Localization." He explained the experiments carried out by himself and assistants on chimpanzees and orangs. After opening the skull and applying the Faradic current motor responses were most marked in the precentral convolution, while the postcentral was apparently silent. Practically the same results were obtained by ablation experiments. Conjugation of the eyes was obtained by stimulation of the frontal lobe, while the occipital gave more pronounced asymmetrical ocular movements. The complexity of the brain, as evidenced by the conformity of its convolutions, approaches somewhat closely that of the human type.

Doctors' Income in London.—Correspondence just printed in the newspapers calls attention to the smallness of the salaries paid to house physicians in London hospitals. Out of twenty examples selected, the average salary is about $370 a year, in addition to board and lodging. At St. Bartholomew's Hospital, one of the largest in London, not only is no salary paid, but the hospital doctors have to pay their own living expenses. The result in all cases is the selection of physicians according to the money they have and not through fitness, as only men possessing private resources are able to take hospital posts. There are many instances where excellent men have thus been excluded from appointments which are filled by less skilled young doctors who happen to be wealthy.

Peace in Leipzig.—The conflict raging between physicians appointed by the State and independent physicians has been settled in favor of the independents. A committee of arbitration with power will wind up all unsettled matters. The appointment of district physicians is indefinitely shelved, and families are free to engage any practitioner of medicine at five marks per year for each individual.

OBITUARY.

Dr. Frank P. Blair, of Allegany, N. Y., died last Saturday night of cancer. He was sixty-one years old and had lived in Allegany for eighteen years.

Dr. W. O. Alexander, a well-known physician of Washington, died at his home in that city last Monday in the fifty-eighth year of his age. He was a graduate of Georgetown University and was a member of the well known Alexander family of Virginia.

Dr. Thomas J. Fitzmaurice, thirty-five years of age, of Paterson, N. J., died May 20, from liver trouble. He was graduated from Bellevue Medical School in 1891.

Dr. Alvin M. Woodward, of New York City, died last Friday. He was sixty-eight years old, and was born at Dresden Mills, Me. He studied medicine at Bowdoin Medical College, but came to New York, where he was graduated from the Homeopathic Medical College. For the last thirty years he had been connected with the Protestant Orphan Asylum, Manhattan Avenue and One Hundred and Fourth street.

Dr. D. P. Jackson, aged sixty-three years, died at his home in Binghamton, N. Y., last Monday. He was one of the best known physicians in that city, and was at one time health officer there. He also served several years as county coroner.

Dr. Edwin Gaillard Mason, of New York City, died last Tuesday at the home of his father, Dr. A. S. Mason, at Hagerstown, Md. He was thirty-nine years old, received his medical degree at Bellevue, and was assistant professor of nervous diseases at the New York Polyclinic School for several years. He was editor of *Gaillard's Medical Journal* for eight years. For fourteen years he practised in New York, and since 1900 had been Vice President of the New York County Medical Society. He was also a Vice President of the Southern Society of New York.

CORRESPONDENCE.

A NEW ROUTE TO THE UTERUS.

To the Editor of the Medical News.

Dear Sir: Perhaps you may be able to find place in your columns for the following for the benefit of pelvic surgeons: A widow woman, resident of New York, lately underwent an operation for removal of a fibroid tumor of the uterus. Removal of the growth took place through an anterior abdominal incision which left the usual scar. In discussing this phase of the matter one of her female friends exclaimed that it was all wrong for her to have submitted to such an operation. "For," she said, "the best surgeons nowadays never remove a tumor that way, but reach it by cutting through the pajama, when of course there is no scar."

New York, May 13. Frederic Griffith.

IS SUBSTITUTION LEGALIZED?

To the Editor of the Medical News:

Dear Sir: The dismissal of the case of Laturen vs. The Bolton Drug Company by Mr. Justice Gaynor, one of the judges of the Supreme Court of this State, on Tuesday, April 19, is an occurrence which should be of great interest because of its vital importance to the entire medical profession. The decision of the learned justice, in the case at bar, deals directly with the question of the right of the druggist to substitute, at his will or convenience, the ingredients called for in the physician's prescription. Under this decision, the person, who in the future may suffer in consequence of such substitution, must regard his chances for the relief which he may seek in a civil action for damages, as practically hopeless, and unless he may find proper redress by having recourse to the criminal courts, there would seem to be no remedy for him against the evil of the substitution of drugs in physician's prescriptions, unless such remedy may be obtained through the means of special legislation. If the final adjudication of this case sustains the action of the learned Trial Justice, then may the druggist dispense the physician's prescription in any manner which may suit his pleasure because, the decision, as it now stands, strikes a blow which shatters to its very foundation the fundamental principle of usefulness of the physician's prescription as a specific order to the druggist, the very nature of which order should make it binding and inviolate.

The plaintiff in the action, in her complaint to the court, alleged that she sent a prescription to one of the

defendant's drug stores for the purpose of having it dispensed and that owing to the fact that a certain substitution was made in the course of its preparation, she received, with each dose of medicine administered to her, double the quanity of heroin which was actually prescribed, together with a certain quantity of morphine, which was not prescribed for her at all, and that in consequence of which substitution and addition, she was made very ill and suffered from opium poisoning.

The defendant corporation interposed an answer which admitted the substitution and which also admitted the addition of the morphine, leaving the question of the measure of damages to be determined. The matter came on for trial in the Court House at Kings County, before Mr. Justice Gaynor and a jury, on April 19, 1904. The plaintiff swore to having obtained the prescription from her physician and further testified that she gave it to her son whom she sent to the defendant's drug store for the purpose of having the prescription "put up." She testified to the fact that when her son brought the bottle, containing the medicine, to her, she took it according to directions, and that the illness followed. She produced in evidence, properly numbered and labeled, the bottle of medicine in question. The plaintiff's son testified that he took the prescription to the defendant's drug-store and that after obtaining the medicine from the manager of the store, the bottle was given directly by him to his mother.

The husband of the plaintiff corroborated her sworn statement as to her illness, further testifying that he had been in constant attendance on her during her entire indisposition.

The family physician testified to having written the prescription and also to his having professionally attended the plaintiff twenty-four hours later. He swore positively that he found her suffering from acute opium poisoning, and described to the court her symptoms, with considerable detail.

The plaintiff's counsel placed on the witness stand the manager of the defendant's store, who swore that he, himself, had dispensed the prescription in question, and the identical prescription was produced by him in court and identified. He swore further that he had made the substitution, and also that he had added morphine when none was prescribed.

Mr. Justice Gaynor having, himself, interrogated the druggist as to what, in *his* opinion, was a safe dose of the medicine to be administered, promptly dismissed the complaint.

The mere question as to whether the plaintiff or defendant should succeed in a litigation of this character is insignificant when compared to the great principle involved. Shall the druggist, in the dispensing of a physician's prescription, be permitted the liberty of substituting drugs other than those called for? This is the question which is interesting to us as physicians and any action emanating from the Supreme Court of this State, which has bearing on it, must, of necessity, receive the consideration at our hands to which it is justly entitled.

Owing to the fact that I wrote the prescription which enters largely into the subject of this litigation, and also owing to the fact that I professionally attended the plaintiff in her illness which resulted from the administration of the substituted preparation, I was subpoenaed as a witness to testify at the trial. I was, therefore, present during the entire court proceedings and observed all that occurred on that occasion.

I am also quite familiar with all the facts and circumstances which led up to the beginning of the action. As a full knowledge of these facts and circumstances is necessary to a complete understanding of the situation, I beg permission briefly to relate them, and as the matter has now become one of public record, I will not hesitate in my statement to mention the names of the persons concerned.

The plaintiff, Mrs. Emma Laturen, is a married woman, residing with her husband in the Borough of Brooklyn. She is the mother of three children, the oldest being a boy who is about seventeen years of age and who is a pupil at the Commercial High School.

I have regularly professionally attended the plaintiff's family since her marriage and I was her mother's family physician before that time. During all these years of my professional observance of her I have naturally become well acquainted with her peculiarities of constitution, together with her idiosyncratic tendencies, and very early in her married life I was made aware of the fact that morphine was, to her, a poisonous drug.

For some months prior to April, 1903, she suffered from metrorrhagia, consequent on the menopause. Her hemorrhages were profuse and prolonged to the extent that she became very weak and markedly anemic.

During the month of March, 1903, she suffered from a very severe uterine hemorrhage which confined her to her bed for a number of days. During her convalescence from this attack she was unfortunate enough to contract an acute bronchitis, which was accompanied by a cough so distressing and harassing in character as to materially interfere with her sleep, and further increase her general weakness and discomfort.

In this debilitated condition Mrs. Laturen dragged herself to me at my office on the sixteenth day of April, 1903, and requested me to give her something to relieve her cough. I observed that she was very pale, presenting an almost bloodless appearance, and also that she showed other evidences of marked debility. Remembering that morphine affected her badly I determined upon the administration of small doses of heroin combined with stimulating expectorants. I therefore wrote for her the following prescription, at the same time giving her proper verbal instructions as to its use.

℞ Elix. Pinus Comp. cum Heroin.....℥
(Merrill's)
S. One teaspoonful in water every four hours.
Cruikshank.

That same afternoon, namely, on April 16, 1903, her son took this prescription to the drug store owned by the Bolton Drug Co. situated at the junction of Sixth and St. Marks avenues, this borough, for the purpose of having it dispensed. The prescription was handed to Mr. Wilson, who is the manager of the store. After a reasonable length of time a bottle was handed to the boy who took it home and gave it to his mother, whereupon she immediately took a teaspoonful of its contents. About half an hour after taking it she became sleepy and drowsy, and suffered from nausea and vomiting. These symptoms persisted, the nausea and vomiting recurring whenever she attempted to raise her head from the pillow. After having slept for several hours she awoke and her cough being troublesome she took another dose of the medicine, having no suspicion at this

*Each fluid dram contains

White pine	2½ grains
Balm Gilead buds	2 "
Spikenard	2 "
Wild cherry bark	1¾ "
Ipecac	¼ "
Sanguinarine nitrate	1/64 "
Ammonium chloride	½ "
Chloroform	½ minim
Hydrochlorate of heroin	1/24 grain

time that it was responsible for her condition. Shortly after taking the second dose the drowsiness and the other symptoms, which have been described, became more pronounced. The patient says she "felt as if she were floating off into space," and was unable to raise her head from the pillow on account of the increased nausea and vomiting which such action produced. When aroused from her drowsy condition she would make attempts to get up out of bed but was unable to do so owing to the combined feelings of weakness, drowsiness, headache, dizziness, nausea and vomiting. To make matters worse, her vomiting had the effect of producing a recurrence of her uterine hemorrhage. About noon, the next day, namely, on April 17, she had sufficiently recovered from these symptoms to realize that her cough was still troubling her and suspecting that the medicine was "too strong" she reduced the dose, taking about one-half a teaspoonful. This dose was repeated several times and as the symptoms which have heretofore been described, reappeared, her son brought the bottle to my office with the request that I should see if it contained "the right medicine." A glance at the bottle was sufficient to convince me that there was a decided difference between its contents and the medicine which, under the prescription, it ought to contain.

I, therefore, communicated with the Bolton Drug Company by telephone, and had a conversation with Mr. Wilson, the manager of the store who informed me that he had himself dispensed the prescription. Mr. Wilson further informed me that when he received the prescription he did not have in stock the article which it called for, namely, the compound elixir of pine with heroin (Merrill's) and so he used as a substitute the compound elixir of pine to which he had added one-twelth of a grain of heroin to each teaspoonful.

I thereupon asked him if he were not aware that the prescription called for one-twenty-fourth of a grain of heroin to each dose instead of double that quantity. He replied that he was not aware of the fact and also that he possessed no actual knowledge as to how much heroin the prescription should contain. I then suggested to Mr. Wilson the advisability of immediately dispensing the prescription as it was written in order that the medicine might be sent to Mrs. Laturen, at the same time telling him where he could obtain the proper preparation. (Shortly after this conversation occurred, a neighboring druggist received an order from the Bolton Drug Company for four ounces of compound elixir of pine with heroin (Merrill's) which order was properly dispensed. That same evening a bottle was delivered at the residence of Mrs. Laturen from the Bolton Drug Company, the label on which bottle corresponded exactly with that which was attached to the bottle containing the substituted mixture, but the difference in the general appearance of the two preparations was very marked.)

During this conversation I asked him to read to me over the telephone, the formula of the preparation to which he had added the heroin. Mr. Wilson thereupon read to me the formula as requested and seemed surprised when he discovered that it showed one-sixteenth of a grain of morphine acetate to each fluid dram.

It will, therefore, be seen, according to Mr. Wilson's own statement, that Mrs. Laturen received twice as much heroin as was prescribed for her in addition to which heroin she received one-sixteenth of a grain of the morphine acetate with each dose.

When Mrs. Laturen's idiosyncrasy is considered it is not hard to account for her distressing symptoms.

As soon as possible, after I was informed of the substitution, namely, on the evening of April 17, I visited Mrs. Laturen. I found her in bed. She was very drowsy, answering my questions very slowly and frequently breaking off an answer in the middle of a sentence. Her pupils were contracted, her respirations were lowered, and she was suffering from nausea and vomiting, the nausea being most distressing when the patient was raised in bed. Her pulse was full and much slower than normal and altogether she presented a picture quite characteristic of acute opium poisoning Strychnine, ergot and atropine were given hypodermically and the administration of the medicine was discontinued.

The next day she was better but very weak. Her nausea lasted for two or three days and her general weakness confined her to her room and residence for several weeks. Owing to the debility consequent upon her metrorrhagia her convalescence was slow, and it was several months before she entirely recovered her normal health and strength.

Mrs. Laturen was very indignant concerning the treatment to which she had been subjected at the hands of the druggist and after consultation with her husband, she decided to bring a civil action for damages against the Bolton Drug Co. Through her attorney, Mr. Edmund F. Driggs, of the New York bar, an action was brought and was disposed of by Mr. Justice Gaynor in the manner already described.

It would be interesting to know exactly by what process of reasoning the learned court, in its judicial wisdom, decided to dismiss an action of this character. Perhaps the following abstract from the stenographer's minutes of the trial will tend to throw some light on this phase of the case:

By the Court: "The evidence in this case is, at the most, that the amount of morphine in this drug, as put up by the pharmacist, was light, one-tenth of a grain to a teaspoonful. There is no evidence here that an excessive dose of morphine was put up. I dismiss the complaint. That it had an unusual effect on this woman is not enough."

In view of the medical testimony, this is a remarkable opinion, and can be accounted for, it seems to me, only under the suggestion of misapprehension.

The language of the court, in its dismissal of the case, expressly calls attention to the fact that morphine was dispensed whereas the evidence shows that no morphine was prescribed. What then had become of the physician's prescription? The learned judge was constantly laboring under the impression that morphine and heroin are identical, whereas nothing can be further from the real fact, as a reference to any medical authority will show. The two drugs are as distinct as they can be, both in their chemical constituents, and in their therapeutic effects.

Even if the drugs were identical the learned court says distinctly that one-tenth of a grain was dispensed whereas the prescription calls for one twenty-fourth of a grain. Is it possible that the prescription is to be ignored and that human lives are to be placed in jeopardy in this reckless manner? Is it true that the courts will permit the patient to be deprived in this way of the physician's knowledge and skill and also that his services are to be superseded by the druggist who can have no knowledge of the general subject? Is there no contractual obligation in the premises? If not, the physician has arrived at a period of his professional career when he must, of necessity, dispense his own prescriptions in order to prevent the poisoning of his patients by the dispensing druggist.

"There is no evidence here," says Mr. Justice Gaynor in his opinion, "that an excessive dose of morphine was put up." Let us see for a moment what the evidence in the case really is on that point.

Abstracted from the testimony of Dr. Cruikshank.

. . . "I found the patient suffering from acute opium poisoning. Her pupils were contracted, her respirations were lowered, and she was drowsy. She suffered from nausea and vomiting particularly when her head was raised from the pillow. Her symptoms were characteristic of an overdose of opium."

If the courts have some mysterious way by which they are enabled to diagnose an "excessive dose of morphine" except by means of the sworn testimony of medical men who describe the symptoms and other clinical phenomena, I have never been made aware of it. I can speak only for the medical profession. In this case, however, the learned justice held that the testimony of the druggist who had actually made the substitution, was admissible and guiding to the court as to whether or not for this particular patient, a safe dose of the combined alkaloids of opium had been dispensed. Of course, the druggist could not in any possible way possess knowledge of her physical condition, nothing whatever concerning her susceptibility to the effects of drugs; no knowledge whatever about the age of the patient, whether a child or an adult; in fact, no therapeutic knowledge as the result of theoretical training or clinical experience, and a thoroughly interested witness in every sense. A witness who so far forgot his relation to the court as to misinform the learned justice by swearing that the prescription concerning which he is testifying, calls for a "patent medicine," when, as a matter of fact, the medicine prescribed is a strictly ethical preparation, the full formula of which is printed on each label. A preparation which is manufactured by a chemical house of over seventy-five years' standing —a house well known all over the United States and in Europe for the strict integrity of its pharmaceutical products. The witness might as well have told the court that Squibbs' compound tincture of opium is a patent medicine. There would have been as much truth in the one statement as in the other. When asked by counsel if the preparation in question is "known," his answer is, "No, not known to the trade in that section of the town," meaning the portion of the city in which the store in which he is employed is situated. Of what value is the testimony of a witness, as to an overdose of opium, who swears that the emetic dose of ipecac is one-quarter of a grain, that morphine will have the same effect upon the weakened and debilitated as upon the strong and robust, who informs the court that one-quarter of a grain of morphine given every hour "might upset a patient?"

At this point, absurdity having reached its height, I prefer to quote the testimony of the witness from the stenographic minutes of the trial:

Q. When you added the heroin, one-twenty-fourth of a grain to a teaspoonful and one-sixteenth of a grain morphine acetate, how much morphine does that make? A. About one-tenth of a grain to the dose.

Q. So that this prescription as you put it up and delivered to this plaintiff contained about one-tenth of a grain of morphine to each teaspoonful of fluid? A. Right.

Q. Is one-tenth of a grain of morphine to a teaspoonful of fluid, administered once every four hours, a safe dose? (Objected to as not coming from an expert.)

The Court: I will take if he knows. (To the witness) You are a licensed chemist, are you not? A. I am a licensed chemist.

By Mr. Nadal: Q. Is that a safe dose or not? A. Yes, sir, perfectly. (Same objection, ruling and exception.)

By the Court: Q. How high a dose would be injurious for an adult? A. One-quarter of a grain every hour might upset a patient.

Mr. Nadal: Q. One-quarter of a grain? A. Yes.

By the Court: Q. Might upset them? A. Put them under the influence of morphine. (Same exception.)

By the Court: Q. One-quarter of a grain every four hours would upset them? A. Every hour.

By Mr. Driggs: Q. You mean an adult person in health? A. An ordinary adult—every adult.

Q. How about a woman already weakened with hemorrhages; would it have a greater effect upon such a patient than upon a patient in health? A. What, a quarter of a grain?

Q. Yes. A. I don't think it would.

By Mr. Driggs: Q. Who do you mean considered this to be a safe amount—yourself?

Q. Did you know what was the matter with this lady at the time you took this prescription from her? A. No.

Q. Did you know that she was very susceptible to morphine? A. No.

Q. You gave her something which contained morphine? A. Heroin is morphine in form.

Q. Did you know that this Elixir Pinus Compositus Merrill's contains morphine, one-sixteenth of a grain? A. Yes, sir.

Q. And this is what you used, adding to it one-twenty-fourth of a grain of heroin? A. Yes.

Q. You take this heroin, one-twenty-fourth of a grain to the teaspoonful and then this morphine in the bottle you take it from, one-sixteenth of a grain to the teaspoonful, is that a large dose of morphine? A. No, sir. (Excepted to as not coming from an expert.)

Q. I understand you to know the properties of these drugs and their effects, do you? A. Yes, sir, I do.

Q. What kind of a dose would these two combined make? A. A perfectly safe dose.

By Mr. Driggs: Q. How do you know the effects of morphine on the human system? A. I take it from the National Dispensatory.

Q. You never had a medical education, had you? A. No.

Q. You are not a physician, are you? A. No.

The learned Court, in its opinion, further says: "That it had (meaning the medicine) an unusual effect on this woman is not enough."

Let us see if we can throw any light on what his honor is pleased to call an "unusual effect." That the medicine had the effect of making the plaintiff sick is conceded in this part of the opinion. Just here the following testimony of Mr. Wilson becomes still more interesting:

Q. When you received this prescription, what did you do? A. I called up our main store, No. 456 Fulton street, to ascertain if they had Elixir Pinus Comp. with Heroin (Merrill's); they said no; then I called the doctor up to find out what dose of heroin he intended to be added.

Q. Doctor who? A. Dr. Cruikshank; he was not there and I took the liberty to give what was considered a perfectly safe dose, which is one-twenty-fourth of a grain of heroin to a teaspoonful.

Q. One-twenty-fourth of a grain to a teaspoonful? A. Yes, sir.

By the Court: Q. That is a safe dose? A. Yes, sir.

Q. You are sure you put no more in? A. Yes, sir.

Q. How many grains did you put in the bottle? A. A grain and a half.

By Mr. Nadal: Q. And that you added, as I un-

derstand you, to the Elixir Pinus Comp., you already had? A. Yes, sir.

Who is to say, in the face of this evidence, what amount of opium or what preparation of that drug was finally administered to the plaintiff? In the preparation of prescriptions, in the manufacture of pharmaceutical products and also in the combining of chemicals for human consumption, much depends upon the manner in which the drugs are put together. Pharmaceutical chemistry is a special branch of science which deals with very important questions along this line. During the past quarter of a century this branch of the work has made advancing strides until it has reached almost perfection. The retail druggist is no longer called upon, with his crude and limited methods, to manufacture preparations which eventually become the ingredients of physicians' prescriptions, to the extent that was required of him in former years. In this work he has been succeeded by the large chemical houses which employ the services of the best pharmaceutical chemists they can obtain, regardless of expense, with the result that the consumer is enabled to obtain much more efficacious and palatable medicines than ever before in the history of pharmacy. This is particularly true of those preparations manufactured in the United States. The physician is thereby enabled to administer to his patient medicinal therapeutic agents which are manufactured by large and responsible pharmaceutical and chemical manufacturing establishments, the names of which establishments are sufficient guarantee of accuracy of preparation and chemical purity. It is fitting, therefore, that some attention should be given to the manner in which this prescription was prepared. Did the druggist dispense heroin proper in his substitution, or did he use the hydrochlorate of heroin? If the former were used an insoluble and consequently a more dangerous drug was added to a salt of morphine already in solution, neither of which drugs was intended for the patient's use, and neither of which was prescribed for her. If the latter, namely, the hydrochlorate of heroin (the drug which the patient should have received) was in a haphazard way added to the expectorant mixture, the tannin contained in the wild cherry bark and other vegetable substances which formed a part of that fluid, would in all reasonable certainty be chemically acted upon and a tannate of heroin, which is an unknown quantity in medicinal therapeutics, be formed.

Thus it will be seen that nothing short of a careful quantitative chemical analysis can, by any possibility, determine what preparation or what dose of opium reached the plaintiff in this case, once the substitution which has been testified to was made. The fact remains that the druggist dispensed, instead of a perfectly clear mixture, which should appear bright red in color, a thick, muddy looking fluid, which he, himself, swears contained heroin *itself* in addition to morphine acetate. Is it then unreasonable to conclude that the learned justice misunderstood the real situation when he stated that there was no evidence that an excessive dose was "put up"?

The courts should be intolerant of intrusion upon the physician's prescription by the druggist. The sick and helpless should not be surrounded with the spirit of commercialism which has become so prevalent and far-reaching in the dealing with matters appertaining to public welfare. Our very system of jurisprudence would seem to be on trial in the adjudication of matters of this character. To allow the physician's prescription to be tampered with and violated in the manner which the evidence proves to have been the fact in the case under consideration, is a retrogressive step in our civilization which is a serious menace to the community. Very truly yours,

William J. Cruikshank.

102 Fort Greene Pl., Brooklyn, N. Y.

SOCIETY PROCEEDINGS.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held February 10, 1904.

The President, Otto H. Schultze, M.D., in the Chair.

Hemorrhagic Meningoencephalitis.—Dr. M. G. Schlapp presented a specimen taken from a case of hemorrhagic meningoencephalitis in a child sixteen months old. The child had been well until December 25, when it developed a cough, an acute foul-smelling rhinitis lasting four or five days. At the end of this period convulsions appeared on the left side, involving the left leg, arm, and face, later on spreading to the right side. It had previously been noticed by the mother that the fontanelles had bulged very much. The child had edema, most marked about the eyes, nose and forehead. This lasted only for about an hour and then disappeared. The convulsions grew worse and the mother took the child to a hospital where the fontanelles were punctured, showing a collection of fluid, but no change of anything else was noted. As the child grew worse, clonic and tonic convulsions developed. The child practically remained in a tonic convulsion. Acute hydrocephalus was diagnosed. About one and one-half hours after puncturing the fontanelles, the child died.

The autopsy was performed by Dr. Schultze, who was allowed only to open the cerebral cavity. He took out the brain and found a hemorrhagic area extending from the frontal pole to the precuneus on both medial surfaces, and laterally the hemorrhage extended about one and one-half inches from the longitudinal fissure. This hemorrhage discolored the brain. In the longitudinal sinus was found a thrombus. It did not fill out the sinus completely. Most of the veins extending laterally from the longitudinal sinus were thrombosed. This condition on section looked exactly like cases described as non-purulent hemorrhagic encephalitis. The hemorrhage was confined to the cortex of the brain, giving the peculiar dotted appearance of the non-purulent hemorrhagic encephalitis. It could be mistaken for this type of encephalitis. The thrombus of the longitudinal sinus most likely caused the condition and was probably an infectious one. Besides hemorrhage and thrombosis there was a meningitis extending over the greater area of the brain. It was not confined to the hemorrhagic area, but extended to apparently normal areas. This meningitis was of the cellular type made up of round cell infiltration, mononuclear leucocytes, not pus cells. It was likely that the meningitis was caused by the same condition that caused the thrombus, or the thrombus was secondary to the meningitis. It was possible that this infection might have passed through the lymph spaces, Pacchionian bodies, into the longitudinal sinus, in that way producing thrombus. It might have been produced through the blood vessel in the same way the meningitis was produced. Round cell infiltration around the blood vessels and meninges was well shown.

Hemorrhagic Myelitis.—Dr. Schlapp also showed a specimen from a case of this affection in a man, forty-eight years old, who two years previous to this attack of myelitis had had an attack of malaria. His-

tory of syphilis, alcoholism, etc., negative. About two months before this trouble came on he had an orchitis from a trauma. The testicle was very much swollen. It was removed by a surgeon in California. The surgeon had told him that the nature of the lesion was tuberculous. The wound healed and he felt fairly well after the operation. He took a trip to the mountains where he strained himself walking and driving over rough roads, and after a particularly long drive he had chills and felt weak in the legs. Then numbness was felt in the soles of the feet and gluteal region. The numbness disappeared and the man came East. While here the numbness again came on and in two or three days it extended from the plantar surface of the feet up to the medial part of the thigh. The gluteal region was also involved. When seen by Dr. Schlapp the man had no definite objective symptoms, although at that time it was suspicious of beginning myelitis. There was no temperature and the pulse was regular—80 to 84. The man was put to bed and watched. The day after Dr. Schlapp had seen him, he developed a subnormal temperature—97° to 96.8° F. This kept up for several days. In the meantime the numbness grew worse and objective symptoms appeared; there was sensory disturbance, marked pain, and temperature, sense disturbed and ataxia; later complete anesthesia below the knees, spreading up the legs and body to the region of the navel; remained one or two days in this condition and then spread to the arms and the man died of a condition resembling paralysis of the vagus and respiratory and heart centers. One and one-half days before death he developed a temperature of 103° F; before that it had been subnormal. On autopsy, Dr. Elser found cirrhosis of the liver and pneumonia, which had existed several days before his death. He had had also acute parenchymatous nephritis. The bones of the spinal column were normal; no infectious condition from that source. No meningitis, no disturbance of the pelvic organs. The spinal cord from the second lumbar segment to the fourth cervical presented small hemorrhages throughout all the tissue; white and gray matter was affected alike. The area of hemorrhage varied in some places more than in others less marked, but distinctly involving the tissue of the cord. At that time the case was diagnosed (and subsequent histological examination verified this conclusion) as non-purulent hemorrhagic myelitis. No meningitis. These hemorrhagic conditions of the cord, Dr. Schapp said, were not very common and the question arose, What was their cause? Cultures were made but they were negative. A Gram stain made of a section was also negative. Nothing definite was found in the section. A drawing of a section of the cord was shown.

Dr. Noyes, in the discussion, said that the first case would be extremely interesting if a report of the cerebrospinal fluid or blood from the ventricle had been made. He understood that this had not been done. In a case reported to the Neurological Society, Dr. Brooks had spoken of the difficulties of diagnosis of hemorrhagic meningoencephalitis, and careful examination of the cerebrospinal fluid sometimes facilitated this diagnosis. Much careful work had been done in the city on the cytology of the cerebrospinal fluid during the last few months. Recent articles in some French journals report that in almost all hemorrhagic conditions, such as hemorrhage into the ventricle, and hemorrhagic encephalitis, the cerebrospinal fluid showed a reddish discoloration of the serum or red corpuscles; and this phenomenon frequently makes a positive differential diagnosis possible. Dr. Schlapp had spoken of infiltration of mononuclear leucocytes of the tissues. It was interesting to compare the presence of lymphocytes in the cerebrospinal fluid and blood with the presence of the same type of cells in the tissues, lymphocytes in the fluids being chiefly found in certain classes of cases, as syphilis or tuberculosis, while polynuclear cells indicate acute infections. Whether this coincided with what could be demonstrated with sections, or how far it occurred with types of leucocytosis in general, Dr. Noyes did not know. The diagnosis of meningoencephalitis though rather difficult could be made by excluding the more common general and local lesions of the brain. It was sometimes found at autopsy where other diagnoses had been made.

In regard to Dr. Schlapp's second case, Dr. Noyes said it was extremely interesting because so many of those transient cord conditions are met with in cases where paralyses have come and disappeared, and one can only infer that some vascular lesions have occurred. Possibly the vessels may have been obliterated but the changes may not have gone so far as the cases Dr. Schlapp had shown. Probably lesions of this type occur more frequently than is supposed.

Dr. Schultze said the cases were also interesting from a medicolegal standpoint. As far as his own experience went he thought the occurrence of a true hemorrhagic type of inflammation rare. The cases which Dr. Schlapp had described might readily be mistaken for cases of trauma unless that condition were kept in mind. It was possible for an inflammation of the pia and the brain or cord, or for a thrombosis of the longitudinal sinus, to produce a condition which might be mistaken for laceration of tissue with subsequent hemorrhage.

Dr. Schlapp said that he considered the remarks made by Dr. Noyes as important, as to lumbar puncture in the second case. In the first case he thought diagnosis would have been made before if the physician had taken the mother's report. She said the child developed convulsions on one side, then on both. The child had edema of the tissues of the frontal bone over the eyes and eyelids. This, he thought, would have led the physician to think of thrombus of the longitudinal sinus at once. If the eyes had been examined a protrusion of the central vessels of the eyes would have been observed.

Teratoma of the Broad Ligament.—Dr. Ferdinand M. Jeffries said, in presenting a teratoma of the broad ligament, that he thought the specimen of more than usual interest. He thought it unique in character. It was taken from a girl of seventeen—a virgin. The history dated merely two days previous to the operation, although since the operation, when the growth was removed, the surgeon had gleaned the fact that the girl had been troubled for some time with constipation and that she was very easily fatigued, and on some occasions suffered considerable pain which was supposed to be in some way connected with the constipation. Two days previous to the operation the girl consulted her family physician, but it was merely for constipation. He gave her some laxative. Next day he called, and found the patient in distress with no action of the bowels, and upon examination found an enlargement of the left inguinal region, which he had not seen at the first examination. He did some manipulation and increased the laxative dose. The next day he was called in great haste and told that quite an enlargement was noticeable in the left inguinal region. Then he called in a surgeon. There had been, up to that time,

no action of the bowels. The surgeon was at a loss to know what it was, but there had been a state of collapse and temperature previous to his arrival. The surgeon advised operation, and he went in through the cul-de-sac. As soon as he made an incision he found a hematoma. He got rid of the clot of blood and in his search found what appeared to be membrane, and made up his mind that there was pus. He made an incision through the membrane, but instead of pus coming, there was a serosanguineous fluid containing a lot of fat, partially saponified or emulsified. He traced this along and came to the growth shown by the speaker. Although found in the left inguinal region, it was attached to the right broad ligament. The surgeon took the entire growth out through the cul-de-sac of Douglas. It was a cyst about the size of a child's head. It was a body covered with skin, having peculiar toe-like enlargements, some large, others small. There was floating with the fat a quantity of hair. The cyst contained bone and cartilage; the one described as toe-like is a picture of the tarsus bone. Some of these bones were harder and less cartilaginous than others. No histological examination had been made.

Dr. Jeffries also showed a cast of the bronchial tubes, a regular tree from a case of plastic bronchitis, more often seen in pictures than in reality. He also showed a sample of urine of unusual interest. It had been put under the microscope. It was urine filled with amebæ. At first it was thought that they might be due to water used to wash the bottle in which the urine was placed, or perhaps the centrifuge or pipette. This urine, in every field the speaker had seen with the one-sixth objective, contained seven or eight amebæ, some exceedingly large, one or two half filling the diameter of the one-sixth objective. The patient was a young man, about thirty-five years of age, who had measles. He had a stricture and his urine contained pus, and apparently had done so for a considerable period of time previous to the present attack of measles. The sample was presented for enlightenment. It was conceivable that there might, in some cases of dysentery, be new channels opened up from the bladder and *Amœba coli* might enter, but he thought these were *Proteus amœbæ*—perhaps there was no difference except in the locality where found. These amebæ did not seem to contain blood cells. He was not prepared to state what bodies were contained. Dr. Jeffries had that day been able to find amebæ in a case of amebic dysentery where he could show blood corpuscles. These did not look like chlorophyl-bearing bodies.

The Bacteriology of the Blood in Typhoid Fever; a Report on Sixty Cases, and a Statistical Study.—This was the subject of Drs. Warren Coleman and B. H. Buxton. The authors made bacteriological examinations of the blood in 60 cases of typhoid fever in Bellevue Hospital, and have collected 544 similar cases from the literature, giving a total of 604 cases. Their practice was to distribute 10 c.c. of blood taken from one of the large veins at the elbow, into four flasks each containing 100 c.c. of broth and to incubate at 37° C. When the cultures were positive they tested the bacilli in glucose gelatine, litmus milk, neutral red agar, and other differentiating media. They were also tested for their agglutinating properties in an active serum. A reaction at 1:100 was considered sufficient for diagnostic purposes. Believing that paratyphoid infections should be considered clinically as cases of typhoid fever they have included in their totals the 23 cases of so-called paratyphoid fever in which bacilli have been found in the blood. Seventy-five per cent. of the 604 cases showed the presence of bacilli in the blood at some stage of the disease, and the authors felt inclined to regard even this as somewhat lower than may be expected in future investigations, since the most recent records, those of Busquet, Courmont and Tesien, show that with the most improved methods the bacilli are practically uniformly present in the first three weeks of the disease. Analyzed by the week in which the examination was made it was found that: (1) Of 85 cases in the *first week* positive results were obtained in 79, or 93 per cent.; (2) of 198 cases in the *second week*, positive results were obtained in 151, or 76 per cent.; (3) of 115 cases in the *third week*, positive results were obtained in 65, or 56 per cent.; (4) of 55 cases in the *fourth week*, positive results were obtained in 18, or 32.7 per cent.

The striking fact brought out by this analysis was the large percentage of positive results obtained in the first week of typhoid fever with the steady decline thereafter. From this it appears that the earliest and principal seat of infection in typhoid fever is the blood. The authors believe that the bacillus disappears from the blood about the end of the third week in the ordinary case of typhoid fever, and that its failure to disappear at this time means the prolongation of the clinical course of the disease.

Twenty-one cases were examined during a relapse, and the bacillus was found in all but three of them. Ten per cent. of the 604 cases presented the bacillus in the blood before the Widal reaction could be obtained. The Widal reaction is often delayed to the twentieth or the thirtieth day; but in one of their cases did not appear until the seventy-first day; hence it was felt that the absence of this reaction by no means justifies the diagnosis of paratyphoid infection. Two of the authors' cases gave the *Bacillus coli communis* in pure culture in the blood. Both cases were mild and the question was raised whether the colon bacillus might cause a primary systemic infection.

Dr. W. Gilman Thompson said an absolutely accurate test would be of great value in an early diagnosis of typhoid fever, and also in those cases in which one may be in doubt later in the disease as between the existence of typhoid fever and some of the conditions for which it is occasionally mistaken, like an obscure case of malignant endocarditis. In regard to the bacteriological examination being of use in very early diagnosis, he asked Dr. Coleman how soon he could guarantee a positive result, if such existed, after obtaining a specimen of the blood.

Dr. Coleman replied in about three days.

Dr. Thompson said that that reduced the value of the result for early diagnosis. If the specimen were obtained on the fourth day, and three or four more days elapsed before results were obtained, the test did not improve on the Widal reaction, which was often apparent by the end of the first week, or upon the appearance of eruption, etc. In that respect he thought the test a disappointment, as an early one to be used as a help in the matter of diagnosis at the bedside. Dr. Thompson had, however, had a number of cases examined at the Presbyterian Hospital, positively demonstrating the presence of bacilli before the Widal reaction was obtained. The Widal reaction had been behaving in a peculiar way. When the test was first used in the city, the speaker was interested in collecting data. He gathered data from other clinicians to the number of five hundred cases. In 93 per cent. of these cases the Widal reaction was found during the active course of the disease, a large percentage being at the end of the first week. With recent tests the reaction was absent in many cases typical, clinically, of typhoid fever, which tests are not returned as positive either from the Health Board or specially trained observers

in the laboratory even after three or four weeks, or perhaps when the patients are in convalescence or relapse. The technic of the Widal test had improved and examiners were reluctant to report a positive reaction until it was obtainable with a much greater degree of dilution than that at first employed. Dr. Thompson believed that bacteriological reaction of the blood could yet be made more satisfactory, and used as an earlier test than the Widal reaction.

The reference of Dr. Coleman to the new aspect in which typhoid fever is regarded—that is, as a blood toxemia—was very interesting, for it afforded an explanation of certain phenomena of the disease, particularly such complications as involved the gall-bladder, periostitis of the rib, phlebitis, etc.

In regard to the paratyphoid germ, demonstration of its presence in the blood was not as yet of any real clinical value in distinguishing the varieties of typhoid fever at the bedside. Paratyphoid had been reported to him by bacteriologists, when he had been entirely unconscious from the clinical standpoint that he was dealing with anything but ordinary typhoid fever. The bacilli of the ordinary typhoid had been found in mild and severe cases, and so it seemed in regard to paratyphoid bacilli. Five cases of apparent typhoid infection had been brought to the Presbyterian Hospital from a tenement house. They were thoroughly investigated by the Health Board from an etiological standpoint; and one which came to autopsy appeared to be typhoid fever, but paratyphoid was reported in two or three of the cases. These cases did not present any clinical peculiarities. This recalls the difficulty in differentiating degrees of malignancy in types of diphtheria and tuberculosis germs. The typhoid bacteriology is interesting in connection with the study of the natural history, in general, of these germs. Dr. Coleman had emphasized the futility of the use of intestinal antiseptics in typhoid fever. The speaker thought the discovery of these bacteriological tests ought to put a final quietus on the attempts to treat typhoid fever with intestinal antiseptics alone. No better proof of this was needed than that brought out by such research as that under discussion.

Dr. Norris asked how many cases of typhoid fever Dr. Coleman had found in which he could not obtain the Widal reaction, and in how many cases he found concurrent infection with typhoid. It was rather hard to draw conclusions from broth cultures because in that medium at no time could the original number of bacilli found in the blood be estimated. It was a favorable medium for the isolation of typhoid bacilli, however.

Dr. Field said that he objected to their considering a disease as a septicemia because microorganisms were found in the blood. Dr. Libman had shown that numerous surgical cases suffering from localized *Staphylococcus aurcus* infections showed many staphylococci in the blood. He thought that they were absorbed from the point of infection and that they did not increase or multiply in the blood stream. In typhoid fever, he said, there were a great number of typhoid bacilli in the intestine, and it was perfectly conceivable that these organisms could find their way into the blood stream by way of the lacteals, especially when there was food undergoing digestion. Where the number of typhoid bacilli per c.c. had been determined they had always been found to be few. In those cases of typhoid fever which have been called typhoid septicemia, the bacilli were present in large numbers per c.c. and the clinical picture was entirely different. The speaker did not think it proper, therefore, to term the disease, as ordinarily seen, a septicemia because a few bacteria were found constantly or in a large proportion of the cases in the blood stream. He did not think that it was in the blood stream that they proliferated and caused that profound toxemia seen in this condition.

Dr. Libman said that he agreed with Dr. Field that typhoid fever should not be considered as a general disease simply because some bacilli were found in the blood. It was different with cases in which there were no local lesions. To illustrate the point that bacteria might be in the blood, even in large numbers, without setting up any secondary foci or seeming to make much trouble, he referred to a case of osteomyelitis of the humerus which he had recently seen. The pus from the bone contained the *Staphylococcus aureus* in pure culture and by means of a blood culture it was demonstrated that there were five hundred colonies of the *Staphylococcus aureus* to each c.c. of blood. After the focus in the bone was opened up the temperature dropped considerably and four days after the operation the blood was found sterile and the patient recovered.

He also thought that it was hardly conceivable that the symptoms of typhoid fever, as a rule, were due to the presence of the bacteria in the blood because so few of them were usually found. He believed that it might be possible to obtain results earlier if inoculations were made from the flasks containing the blood even before any turbidity developed from the growth of bacteria. With the Widal reaction his results had differed from those of Dr. Thompson. The results had been better than those in previous years. During September, October and November, every case of typhoid had given a positive Widal reaction within three or four days after admission.

He believed that the finding of the typhoid bacillus was of importance in establishing the etiology of otherwise obscure conditions. There had been admitted into the service of Dr. Rudisch, at the Mt. Sinai Hospital, a patient suffering for twenty-four hours from symptoms apparently due to intestinal perforation. On operation a localized pus sac was found, a culture from which showed *Staphylococcus aureus* only. There were no typhoid bacilli in the urine or stools, but the blood, two days after admission, was proven by culture to contain typhoid bacilli. The Widal reaction became positive about a week later. In that case the diagnosis would not have been definitely established so early without the blood culture.

Dr. Coleman said that only one or two of the authors consulted made mention of mixed infections in typhoid fever. In a few cases Busquet had found other organisms than the typhoid bacillus; *e.g.*, streptococci, staphylococci and pneumococci.

Dr. Buxton said he had found no evidence of mixed infections in the cultures.

Dr. Coleman agreed with Dr. Field that typhoid septicemia was not a good term, and said that they had used it only to emphasize the fact that typhoid fever was not an intestinal disease, susceptible of modification by means of intestinal antiseptics.

Demonstration of Coagulum Production by Growth of Bacteria in Sugar Media.—Dr. E. Libman said that in a paper published several years ago on the features of the growth of bacteria in media containing both sugars and serum, he had mentioned that he had occasionally seen coagulum production in such media, and had suggested that the phenomenon might become of some importance in explaining the occurrence of some cases of thrombosis in infections, especially in diabetes. Since that time Dr. Flexner had brought up the question of the agglutination of red blood cells as a cause of thrombosis. The flask which Dr. Libman presented contained streptococci growing in a medium containing one-half per cent. glucose bouillon, two parts,

and serum, one part. In it could be seen very nicely the very extensive coagulation, and at the bottom of the flask marked agglutination of the erythrocytes. Central flasks containing no cocci showed no changes after several days.

Some Peculiar Changes in the Fluid of a Pleural Effusion.—Dr. E. Libman said that this fluid when first obtained, by aspiration of a chest in a case of pneumonia, was light yellowish in color and very slightly turbid. Microscopically it contained very few pus cells and some pneumococci. On standing in the thermostat twenty-four hours a precipitate began to form in the tube and the fluid turned greenish in color. After forty-eight hours the fluid was decidedly green, no longer transparent, and there was a heavy, clumpy deposit at the bottom of the tube. Without a microscopic examination one would have believed that the fluid came from a case of empyema. The specimen was shown merely to indicate that certain appearances which are seen in some exudates can develop as a result of bacterial growth outside of the body. It had been observed that certain streptococci could produce a greenish color in media which contained a decided amount of blood and occasionally fluid obtained from the cerebrospinal canal was seen to turn slightly green after standing a few days, but the marked change which the speaker had described, from a practically clear fluid to a fluid resembling closely an empyema fluid, had not, he thought, been noted.

CHICAGO MEDICAL AND ORTHOPEDIC SOCIETIES.

Joint Meeting, held March 30, 1904.

The President of the Chicago Orthopedic Society, Arthur B. Hosmer, M.D., in the Chair.

Multiple Lipomata.—Dr. Weller Van Hook exhibited a man, sixty years of age, with multiple lipomata of the neck. The patient first noticed these tumors nine years ago. At first, they annoyed him on account of the pressure which they made upon his collar button. The tumors at that time were about the size of a pea, but within a year or so they had attained their present size. The patient had not found it necessary, however, to wear a collar of larger size on account of the tumors. At the time of the incision, there was no attempt made to remove the entire tumors, but only portions of them were taken away. This operation was done by another surgeon. The tumors had been practically stationary in size for five years. Dr. Van Hook stated that symmetrical lipomata of the neck region were not very rare, but that this was a pronounced case. Patient had large lipomata in front of the neck which he said was not an unusual concomitant of such cases.

Gunshot Wound of the Olecranon Process.—The next case presented by Dr. Van Hook was one of considerable interest, the patient having sustained a gunshot wound in the month of November, the bullet lodging under the olecranon process. On this account the patient was unable to fully extend the elbow. The X-ray plates were probably the most interesting feature of the exhibit. He made an incision about three inches long, and extracted the bullet without much difficulty. The patient had a marked degree of anchylosis or incomplete motion before the operation, but after the bullet was removed motion improved materially. There was still some incompleteness of motion, but it was gradually improving. The patient was able to swing a sledge hammer.

Double Congenital Dislocation of the Heads of the Radii.—Dr. Van Hook showed a little girl with double congenital dislocation of the heads of the radii upon whom he had operated, saying that such cases were quite uncommon, but not very rare. One of Hoffa's assistants collected 31 cases from the literature. Of 12 cases that came under the observation of Hoffa, 8 were backward dislocations, and 4 forward. In the speaker's case the dislocations were both forward. The arms were in complete extension; no flexion could be effected; but after resection of the heads of the radii, it was possible to get some flexion. There was elongation of the radii which was common in such cases, and this fact prevented flexion at the elbows. The joints were imperfectly developed. The synovial cavities were not sufficiently extensive, and it had been the effort of months of treatment which he had given the case to extend the range of motion in the joints by occasional manipulation under nitrous oxide gas anesthesia. He believed the joint capsules were doing better work now than they did. There was certainly more motion than there was soon after the operations were undertaken. The little patient was now able to put her hand up to her face, which she could not do before treatment was instituted. The operation for the relief of this deformity was performed by Dieffenbach in the earlier part of the last century, when a resection of the entire elbow-joint was done, with fairly good result, and afterward more rapidly resecting the heads of the radii. He said that the heads of the radii had been resected by Hoffa, with good results. Resection of the heads of the radii was indicated in those cases where there was well-marked elongation of the radii, the radius being shortened sufficiently to come into fairly good articulation with the other structures. The etiology of this deformity had elicited considerable discussion. Some had regarded it as due to intrauterine improper position, while others had considered it to be due to unequal and improper growth of the bones composing the elbow joint, and elongation of the radius being supposed to be the etiological factor in such dislocations. The muscles had never sufficiently developed about the elbow joint either above or below; but considerable development had taken place in his case since the treatment was begun last June. In looking up the literature, he stated that Abbott reported before the Pathological Society of London seven cases that had occurred in four generations of one family.

Dr. John Ridlon asked Dr. Van Hook why the arms did not fully straighten. He said that his explanation of not being able to flex them was perfectly clear, but that he did not mention the reason for their inability to fully straighten.

Dr. Van Hook replied that he had kept the little girl's elbows on one occasion for quite a little while in as great flexion as possible, and he thought some contracture was responsible for the inability to extend the arms as completely as at the beginning, but it was his desire to give more flexion in order that the child might reach her face and head rather than to maintain free extension. However, he was in hopes that he would be able to regain the lost extension. In reply to a question asked by the President, Dr. Van Hook answered that the ligamentous structures were imperfectly developed. The ligaments were very thin, and much spread out. It was easy to cut down upon the head of the bone and excise the semi-cartilaginous mass.

Compound Comminuted Fracture Associated with Dislocation of the Ankle-joint.—Dr. L. L. McArthur showed a patient upon whom he had operated for this fracture, which was associated with a dislocation of the ankle-joint. He mentioned how the fracture was produced, and said on admission to the hospital it was found possible to evert the patient's foot on the leg as a hinge, so that the upper surface of the astragalus

and articular surface, or what remained of the tibia, could be completely exposed. Black mud was ground into the deeper portions of the joint. The vessels of the foot were intact. After some hesitation, but reenforced by the statement of the patient that she would rather die than have an amputation, he decided to try and preserve the foot. Under anesthesia it was possible to open the joint as if one was about to make a resection of it, exposing the entire articular surface by simply turning the foot outward on the leg. The fibula was comminuted; the tibia was fractured, and the internal malleolus loosened from the tibia. The broken end of the tibia had the dirt ground into the pores of the bone. The end of the tibia was chiseled off and freshened; the black dirt washed out of the joint as thoroughly as possible, and 95 per cent. carbolic acid swabbed over the entire joint surface for thirty seconds, and following that the use of alcohol until all the whitening effect of the carbolic acid had disappeared. The tibial fragments were wired together; the lower fragment, fortunately being adherent to the internal lateral ligament, by simply wiring it to the shaft of the tibia allowed sufficient fixation of the foot to permit doing without a cast. On the three following days the patient was given three successive doses of the antitetanic serum to guard against the possibility of tetanus developing. It was the author's practice to do this in such cases, and he had done so for seven or eight years. At the end of four weeks the patient left the hospital. The result was excellent. He emphasized the desirability of trying, with the consent and understanding of the patient, to save all limbs in which circulation was good, with the opportunity for a prompt amputation, should it become necessary, afterward. It was absurd to hope much from the antitetanic serum after the toxins had become colligated with the nervous tissue of the spinal cord.

Compound Comminuted Intercondyle Fracture.—The second case Dr. McArthur called attention to was one of compound, comminuted fracture involving the knee-joint, the character of the fracture being oblique intercondylar, with one fragment sticking through the skin. The patient was a sign painter, who fell from a scaffolding, striking with great violence, fracturing his knee, and driving a fragment through the integument. Macroscopic dirt was to be seen on the fragments. The wound was enlarged, and the fragments wired together, a useful joint being obtained. A skiagraph showed the fragments nicely united and the wire *in situ*.

Dr. Hosmer asked whether Dr. McArthur had seen any toxic effects from the use of 95 per cent. carbolic acid in joint injuries, that is, applying it for thirty or forty seconds where there was extensive injury of bone.

Dr. McArthur replied that he had never seen any toxic effects from it. He thought, however, that this was a particularly appropriate case in which to use it.

SYMPOSIUM ON TUBERCULOUS SPONDYLITIS.

Etiology.—Dr. Edwin W. Ryerson discussed this phase of the subject, saying that tuberculous spondylitis was applied to a destructive tuberculous process attacking the vertebræ. It occurred in the anterior portion, or body, of the vertebra, the part which did the supporting and weight-bearing of the upper half of the individual. It practically never affected the rest of the vertebræ, the pedicles, and laminæ, and processes, but the intervertebral discs were often destroyed by the direct extension of the disease. The disease was caused by the local deposit of tubercle bacilli which had been disseminated into the blood current, either from an older focus somewhere else in the patient's body, or from some direct infection of the circulation through the skin or mucous membranes. This latter method was rare, but was supposed by König to have occurred in several cases of joint tuberculosis, where at autopsy no antecedent focus could be found. The usual infection route, however, was undoubtedly through the lymphatic glands, bronchial, mesenteric or cervical, from which the bacilli found their way into the circulation individually or in small embolic masses, and traveled through the blood vessels until arrested by some obscure, determining cause, perhaps a minute hemorrhage due to slight traumatism, or possibly a little defect in the loosely constructed vessel walls, which allowed a mural implantation. The disease was most prevalent among the ill-nourished children of the poor, living in localities where they were exposed to tuberculous infection, in overcrowded and unsanitary dwellings. A large proportion of such children were shown at autopsy to have glandular tuberculosis, even though no clinical manifestations may have existed. Moreover, a clear hereditary predisposition had been demonstrated in from 25 to 70 per cent. of the cases of Pott's disease, the statistics of the different authors varying within those limits. Both sexes were about equally represented, boys being slightly more numerous than girls. Age was a powerful factor, for 85 per cent. of all cases began in the first decade of life, and fifty per cent. between the third and fifth years. No age was exempt, since cases were on record as young as two months, and as old as seventy-seven years. The disease was very common, and formed nearly half of all the various tubercular joint lesions. The portion of the spine most frequently affected was stated by Taylor to be the cervical region, but most other observers considered the junction of the dorsal and lumbar regions to be the most vulnerable. When in the cervical or lumbar vertebræ, the deformity was apt to be smaller and more successfully treated than when in the middorsal region.

Diagnosis and Prognosis.—Dr. John L. Porter said that in no form of tuberculosis did an early diagnosis mean more to the patient than in tuberculosis of the spine. Until the diagnosis was made, efficient, intelligent treatment could not be instituted. With an early diagnosis, not only was the treatment made more effective, and the prognosis improved, but the patient might often be saved a distressing deformity which added to an already crippled existence a burden of mental suffering and pain. He believed that a diagnosis of spondylitis could and should be made in every case before any deformity had appeared; regardless of the age of the patient, in almost every case sufficient additional evidence might be elicited to enable one to decide with reasonable certainty whether it was tuberculosis or not. Stiffness and rigidity of the spinal muscles, limiting the normal freedom of motion, and producing involuntary spasm of the muscles when motion was attempted, were the earliest, the most constant, and the most reliable signs of joint trouble anywhere. He considered the signs and symptoms of spondylitis in detail, with relation to the different divisions of the spine. He believed more failures to diagnose spondylitis were due to lack of careful examination than to lack of knowledge; but he did know that diagnoses of colic, rheumatism, sciatica, or injury covered a multitude of errors. When practitioners remembered that spondylitis might cause any kind of pain, from headache, earache, to sciatica, and when they cultivated the habit of examining the spine for rigidity as carefully as they examined suspicious lungs for tubercle bacilli, the early diagnosis of tuberculous spondylitis would be more frequently made.

In the prognosis of tuberculous spondylitis, one had to consider (1) the factors concerned in the prognosis were the time at which the diagnosis is made and the

treatment begun; (2) individual resistance to the disease; (3) the patient's age; (4) the patient's environment. These, with the location of the disease in the spine, were the chief points in determining the prognosis. Each point was elaborated by the speaker.

Straightening of the Curvatures of Tuberculous Spondylitis.—Dr. John Ridlon, after mentioning the methods of straightening of curvatures in cases of tuberculous spondylitis, related his personal opinions and conclusions, to which he had arrived from his experience, which were: So long as the carious disease was active, and before structural shortening in the muscles and distortion in the ribs had taken place, and before any solidification had occurred at the point of disease, straightening of the spinal deformity was possible by gentle means, *i.e.*, without anesthetizing the patient. When the deformity was still increasing, even if some solidification had taken place, straightening could be made by force in certain regions, namely, where distorted ribs and structurally shortened muscles did not hinder, and in all regions some gain could be had by the use of reasonable force. But when solidification had become complete, or so complete that there had been no increase of deformity for some months, the use of unreasonable force to make the spine straight was to be deprecated. In the cervical region he had always feared to use force to effect straightening. On the other hand, he had never failed to straighten cervical deformity by gentle means, namely, traction during recumbency, in all cases presenting evidence of active disease. In the upper dorsal region it was very difficult to apply force advantageously, and equally difficult to maintain any correction that might be made; and he was of the opinion that gentle traction and prolonged recumbency with leverage would accomplish as much as force. Only occasionally did one effect a straightening in this region; generally one must be satisfied to prevent a development or an increase of the deformity. In the lower dorsal and dorso-lumbar regions, the most frequent site of spinal caries, forcible straightening was most readily effected, and gave the best results. In the lower lumbar and lumbo-sacral regions, it was difficult to maintain any correction accomplished by forcible methods, and it was perhaps as well to treat these cases by traction and leverage. In selecting cases for forcible straightening, one should reject cervical cases as dangerous, upper dorsal cases as too difficult to straighten, and lower lumbar cases as too difficult to hold. Cases where the deformity had not increased for six months or more should be rejected as cases in which the disease had healed; and cases of short duration and no great deformity should be rejected as exposing the patient to unnecessary risk, for these cases could be straightened equally well by gentle methods. Patients that had been subjected to forcible straightening must be kept in absolute recumbency for from eight months to one year at least, and the region straightened must be as carefully immobilized as if fractured. Relapse of deformity to some extent usually occurred, but it was due to ineffective immobilization, careless nursing, or too short a period of recumbency. By gentle methods real straightening was not to be expected in patients who were allowed to sit up and walk around, though sometimes a false straightening could be accomplished; that is to say, the patient as a whole could be made to look straighter, though the actual kyphosis remained the same. The anteroposterior leverage spine brace was effective as a straightening device only in the hands of one familiar with its mechanical possibilities; it was not to be recommended to the general practitioner of medicine or surgery. Combined traction and leverage, though the most effective gentle means, was useless unless the patient was tractable and the nurse efficient. It should never be tried on an unruly patient, or where the nursing was inefficient. For most patients, cared for by the average nurse, and treated by any doctor other than an expert, a plaster jacket put on with the patient on Goldthwaite's frame, or some modification thereof, with the jacket sufficiently long both at the top and bottom would be found the most trustworthy device for immobilization, and when combined with recumbency for a long period, the most satisfactory method of treatment.

The Present Status of the Mechanical Treatment of Spondylitis.—Dr. Wallace Blanchard said that in considering the mechanical treatment of spondylitis it must be thoroughly understood that to get good ultimate results treatment should be begun at the earliest possible moment, and must be persisted in unremittingly until a cure is effected. It is not surprising to meet with a diversity of opinions regarding the utility of the various forms of apparatus, for several surgeons may be equally successful in their ultimate results, each utilizing the appliances with which he is the most skilled. The form of apparatus or method of treatment is of minor importance as compared to a correct understanding of the principles involved, and a firm determination when a case was once undertaken to unremittingly persevere as long as treatment might be necessary. Treatment by recumbency was frequently advisable in the early acute stages, and was occasionally necessary in cases that had become considerably advanced without any adequate treatment and with considerable deformity, with general physical weakness, and more or less advanced Pott's paraplegia. When recumbent treatment was employed it should be faithfully carried out with the view of having the patient on his feet with his spine safely protected in a jacket or brace at an early period. Frequently when the deformity was advancing, the most approved treatment was a combination of plaster jacket or brace with recumbency on any convenient lounging place, and preferably in the open air. The plaster jacket was very largely used and its efficiency had been greatly increased, if not doubled, by the use of the Goldthwaite stretcher frame. The author demonstrated how to apply the plaster jacket by the aid of this frame, and stated that prolonged experience had thoroughly demonstrated that when made and applied with proper skill and care, the plaster jacket and many of the forms of braces were very efficient for the treatment and cure of spondylitis, and that in a great majority of the carefully treated cases the deforming hump could be minimized and largely neutralized, and in a few favorable cases nearly, or quite, obliterated. A set of principles based upon the most approved mechanical means of treatment might be formulated, though the extent to which they could be carried out varied in each individual case: (1) To remove the superincumbent weight of the body; (2) To prevent flexion and rotation of the spine; (3) To put the greatest possible amount of pressure upon, or in the immediate vicinity of, the deformity compatible with the integrity of the skin; (4) To very thoroughly hyperextend the spine. It was believed that the application of these principles placed the spine in the best possible circumstances for healing, with the least possible amount of deformity. The author exhibited a plaster jacket with chin rest; a Taylor back brace with head supports; a brace for cervical spondylitis partially applied, with the chin nearly touching the chest, which was the typical position in advanced cervical spondylitis, and a brace for the treatment of cervical spondylitis.

Gravitation Abscess.—Dr. Alex. C. Wiener discussed this phase of the subject, and presented a patient upon whom he had operated for gravitation abscess. Gravitation abscess was both frequent and difficult to treat. There was a temptation to open these abscesses at the most prominent part and empty the pus, but this did not reach the seat of the difficulty. It only encumbered the patient with permanently oozing fistulæ, which were usually accompanied by mixed infection and amyloid degeneration, followed by the death of the patient. Such abscesses were rarely accompanied by fever, 101° F. being the highest recorded. The ordinary symptoms of sepsis were not present, and under favorable circumstances absorption might take place. He had observed in the right iliac fossa in a man, forty-five years of age, a tuberculous abscess the size of a child's head, which disappeared without leaving a trace. In this case there was a destruction of the first lumbar vertebra, and the only treatment employed was a permanent extension apparatus. Recently he had used, in a large psoas abscess, reaching down to the middle of the left femur, which originated in a tuberculous spondylitis of the first and second lumbar vertebræ, a large trocar to empty the pus. The man, thirty-four years of age, was attacked seventeen years ago with tuberculous spondylitis, which left quite a kyphosis of the lumbar spine. For seventeen years he did not experience any inconvenience, when, without apparent cause, the tuberculous process revived, resulting in a large psoas abscess which bulged forward at Scarpa's triangle. Just behind and below the left great trochanter was found a small swelling the size of a silver dollar. This spot was chosen for three preliminary injections of carbolic acid, six drops each time, five and seven days apart. Carbolic acid seemed to have powerful chemotactic qualities, since it allured, so to speak, the pus to the outer side of the femur. One pint of thick pus intermixed with chunks of fibrinous coagula and fine osseous débris was emptied the first time. Then fifteen drops of 95 per cent. solution of carbolic acid was slowly injected into the abscess cavity. The operation was repeated six times at intervals of one to three weeks. The last injection was made three months after the first one, when the fluid had changed into a clear yellow serum. At no time was there any harm experienced, either local or systemic, and the injections seemed to cause no pain or inconvenience.

Surgical Treatment of Tuberculous Spondylitis.—Dr. A. E. Halstead said that the surgical treatment of Pott's disease comprehended (1) the removal of the tubercular focus in the bone; (2) the treatment by incision or by puncture of the abscesses that are secondary to the bone disease, and (3) the operative treatment by laminectomy of the most serious of all of the complications of this disease, namely, the paraplegia resulting from pressure upon the spinal cord. The treatment of these abscesses by incision did not yield good results because of the inaccessibility of the underlying bone disease. In the cases where there was no hope of following the abscess to its source in the bone, incision should, if possible, be avoided. In this class of cases aspiration of the contents of the abscess cavity, followed by washing out of the cavity and the subsequent injection of iodoform, should be practised. In case of small abscess, one should incise the abscess and eradicate the diseased tissue, as this offered the best hope for a speedy and permanent cure. When the abscess was large, or when it appeared some distance from the diseased vertebræ, as in psoas abscess, puncture and injection of iodoform emulsion should be practised to prevent rupture and consequent mixed infection. He said the post-mortem findings in cases dying from paralysis occurring in Pott's disease presented the strongest argument in favor of laminectomy. It had been fully demonstrated that the paralysis was practically never due to an inflammation of the cord, and that the so-called myelitis was not a myelitis, but a pressure atrophy of slow development. Schmaus and others had shown by a careful study of the post-mortem records that it was only in about two per cent. of the cases that the pressure exerted upon the cord was the result of angularity of the vertebral column. In 32 cases out of 33 reviewed by Schmaus, the pressure was due to the tuberculous process breaking into the spinal cord, the immediate cause being either a tuberculous peripachymeningitis or a tuberculous abscess within the canal. The author's experience in the operative treatment of paraplegia due to spinal caries had been limited to two cases, which were detailed, one of which recovered, and the other died. He said laminectomy was contraindicated in cases in which there was tuberculosis of any other organ. In one of his cases the lung and pleural tuberculosis probably existed before the operation, although its presence was not recognized. The duration of the paralysis offered no contraindication to the operation, as it was not so much the length of time that the cord had been subjected to pressure, as the way in which the pressure was exerted that affected the integrity of the cord and determined the possibility of recovery.

Dr. M. L. Harris, in the discussion, said that the importance of an early diagnosis had been very well emphasized, and the statement also made, which was eminently correct, that mistakes in diagnosis were usually made because of omission on part of the surgeon or the physician to recognize certain points which were well known. These were errors of omission. The rigidity which had been emphasized as the early symptom was present in such a number of conditions about the cervical region that more attention should be devoted to this region in the differential diagnosis than to rigidity in other regions of the body. That is to say, there were so many conditions which might occur about the head and the neck which would produce rigidity of the cervical spine that one must make a differentiation. One of the important points to be observed in rigidity of the cervical spine as indicating the involvement of the spinal column itself was the relief which came from extension. For instance, take a child with a rigid neck, by gently extending the head and relieving the pressure, consequently pain, considerable motion might be given to the head without resistance on part of the patient. If one found relief of rigidity by this extension, it was certain evidence that the trouble was in the spinal column itself. If the rigidity was due to any extraspinal trouble, it was almost always increased by extension and by motion. With regard to the treatment of abscesses, as long as a tuberculous abscess of spinal origin was not increasing in size, he thought it should be left alone, as many of these abscesses disappeared by proper mechanical treatment. Only when they increased in size, in spite of conservative treatment, and when they were approaching the surface and seemed as though they would rupture spontaneously, something should be done by the surgeon. One should always attempt to cure these abscesses by the so-called subcutaneous method first, that is, aspirating them, and after washing them out, injecting them rather than opening them, in order to avoid secondary and mixed infections. In emptying these abscesses by means of a trocar, for instance, great care should be exercised not to produce unnecessary pressure on the abscess, as by so doing one was liable, particularly if the trocar became occluded by the caseous

masses, to infect the tract around the trocar, and one would have spontaneous opening of the tuberculous tract soon after in spite of anything he could do. The trocar should be introduced from some distance, to prevent, if possible, the escape of any of the fluid about the trocar, or following the trocar after it had been in the joint. He had seen infection follow the track of the trocar in a number of cases. He had used carbolic acid for a long time in injecting these cavities; it was preferable, as a rule, to iodoform emulsion.

Dr. Frederick Müller said that early diagnosis in every case of Pott's disease was of the greatest importance, and although we did not have any means of stopping the tuberculous process proper, we might succeed sometimes in restricting the deformity which would always follow the establishment of a tuberculous process in the vertebral column. The treatment which had been advocated was mostly conservative, which supported or extended the vertebral column, thus confining all surgical intervention to the treatment of abscesses and paralysis. Different kinds of appliances and apparatus had been mentioned. They were all useful in treating these cases, and no doubt good results could be obtained by employing them, but he did not think it was possible to give preference to a special brace in all cases. He said the Lorenz apparatus was very effective in these cases. It had more advantages than the Bradford frame, because in the Bradford frame the patients were able to make lateral motion, whereas in the Lorenz plaster bag or apparatus the patient was kept always in the same position. This apparatus consisted of a posterior case of plaster-of-Paris which included the head, neck, back, and pelvis, and was well padded. Dr. Müller then discussed the pathology of the paralysis in cases of spondylitis, and said that Schmaus, of Munich, about ten years ago, found that paralysis in cases of Pott's disease was due to a kind of inflammatory edema, which was caused by the establishment of the tuberculous process in the surrounding membranes of the medulla. This edema might last for years, or it might either disappear or terminate in a real myelitis. If the latter occurred, then the patient had permanent paralysis, whereas in the first instance the motility returned and the patient recovered. He referred to the treatment of Pott's disease as advocated by Calot about eight years ago. As to the treatment of paralysis, he mentioned laminectomy, saying that most of the surgeons who had operated on cases of paralysis by laminectomy had said that the paralysis disappeared independently of the operation that had been performed. He had seen two cases of paralysis in Pott's disease treated by the Calot redressment, and he was convinced that this treatment was very effective for paralysis. At all events, it saved patients from surgical intervention which might be fraught with great inconvenience and serious results.

Dr. Ridlon said, in referring to the remarks of Dr. Harris, that an abscess should not be interfered with unless it made the patient sick, no matter whether it was three inches, or one-eighth of an inch from the surface. If, however, it made the patient sick, it should be removed.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held April 11, 1904.

The President, Thomas E. Satterthwaite, M.D., in the Chair.

Counter-Opening in the Vagina for Artificial Bladder Drainage.—The first paper of the evening, by Dr. Nathan G. Bozeman, was on this subject. He said that perhaps the earliest mention of the procedure for establishing a vesicovaginal fistula for the relief of chronic cystitis was in the registry of the Woman's Hospital, New York, in 1858. In consultation with the patient's physician, Dr. J. Marion Sims, the record states, proposed to make an artificial opening in the base of the bladder for the purpose of allowing the free escape of urine, in the hope that by this means a new action would be set up in the walls of the bladder. Little or no profit resulted from this treatment, however, and in July, 1858, she applied for the closure of the vesicovaginal fistula. Up to this time it is natural to suppose that an artificial fistula had never been deliberately made, because it was only at this period that Drs. Sims and Nathan Bozeman made such advances in surgical treatment that it became easy, and vesicovaginal fistulæ could be closed with more certainty. In his book, Dr. Emmet says that shortly after this colpocystotomy became a recognized treatment for chronic cystitis at the Woman's Hospital, at that time the only public institution for special treatment of women. Having referred to his father's work in the matter of artificial vesicovaginal fistula, Dr. Bozeman said that the problem of artificial drainage had presented itself because of the incalculable advantage it would be to the patient to be freed from the constant dribbling of urine as long as the opening in the bladder was maintained. An instrument was evolved which could be worn in the vagina, having a soft rubber urinal attached by means of a soft rubber tube. The improvements since made in this apparatus have been such as observation and experience in numerous cases have suggested. The cervix uteri and vesicovaginal septum rest upon the concave surface, the close adaptation of these parts and the vaginal walls rendering it self-sustaining. Urine and secretions percolate through round orifices into the interior, collecting in quantities of one-half to one ounce, or more, when they are voided through the tubes into the urinal. The latter may be either attached to the knee or placed in the bed, according as the patient is on her feet or reclining. The vaginal receptacle being once filled, the urine (there being no cushion of air in the tube to impede it) flows quickly out, and subsequently frequent intermittent discharges take place when there is only a small accumulation. (The apparatus was here presented for inspection.)

Dr. Bozeman then cited three illustrative cases in which there were injuries to the walls of the bladder which healed kindly when physiological rest and drainage of the organs was successfully established by means of his air and water irrigator and the vaginal drain. In the first the patient had been operated on at the Johns Hopkins Hospital by suprapubic cystotomy to remove a tuberculous ulcer from the bladder wall. Three months afterward an abscess developed and discharged in the abdominal scar. Through this sinus urine soon escaped, and after three years feces and flatus escaped through it, as well as being voided by the urethra. To relieve the cystitis and constant vesical tenesmus present an artificial vesicovaginal fistula was made, and at the same time a quantity of adenoid growths were removed from the bladder. Continuous irrigation of the bladder was then applied by the Bozeman irrigator for ten days, when a vaginal drain was fitted. Since then, two years ago, the patient has not suffered from bladder symptoms, and she keeps herself free of the discomforts of dribbling urine by wearing the drain continuously. In this case, he said, an attempt to close the fistula would not be advisable even now, because the bladder cavity is much contracted and is constantly filled with adenoid vegetations, which have to be removed from time to time through the fistula. The second case, that of a professional nurse, was one of unusual interest. In 1898 the patient began to have recurrent attacks of cystitis. In

1900, after the voluntary escape of the contents of a painful swelling in the right inguinal region into the bladder, flatus and fecal matter commenced passing by the urethra. Dr. Bozeman made a diagnosis of adherent ovarian tumor on the left side, with a communication between the bladder and intestine through some dense adhesions. He opened the abdomen, removed the cyst, and after tying them by double ligature severed the adhesive bands which were found between the bladder and intestines. Subsequently developments showed that a communication still existed between the intestines and bladder; but it was deep down under the broad ligament and could not be reached by opening the abdomen. After severe constitutional symptoms and local pain had continued for some time, there appeared in the right lumbar region a tumor which was evidently the pelvis of the kidney distended by urine and pus. Having made an opening into the bladder, he passed a catheter ten inches into the ureter, when it met with resistance. This was gradually overcome, and bloody, purulent matter was drawn from the pelvis of the kidney. The opening of the sinus into the bowel was found to be located by the side of the urethral orifice. The catheter was left in place twelve hours, the tumor subsided and the symptoms abated. In a short time no more gas or fecal matter passed into the bladder, and the urine became clear. Considering the debilitated condition of this patient, he might have hesitated to perform the operation he did had he not felt positive that he could keep her perfectly dry by means of his irrigating apparatus. She now wears the drain as she goes about her duties as nurse, but she hesitates to have the opening in the bladder closed. In the third case there was an opening in the bladder wall, about an inch and a half in diameter, which was the result of sloughing following an operation for the relief of an inguinal hernia with incarceration of intestine and bladder, with firm adhesions in the inguinal canal. An attempt had been made to close the fistula, a catheter being retained in the urethra for drainage, but it resulted in failure. Dr. Bozeman, having been called to see the case, first established a vesicovaginal fistula, and then, with much difficulty, dissected the bladder free from the densely indurated borders of the suprapubic opening. This was closed by a continuous chromicized catgut suture, and a second row of silkworm-gut sutures brought the muscle and integument as well together as it was possible to do. After the operation his continuous irrigator was employed, and the suprapubic opening soon healed. After ten days a drainage instrument was adjusted, and at the end of ten weeks the artificial vesicovaginal fistula was closed. The attempt to drain the bladder in this case by simply making a vesicovaginal fistula would have proved futile. In conclusion, he maintained that in all cases, after an artificial fistula has been made into the vagina, a system of irrigation and drainage similar to that described is absolutely necessary, both for its efficacy and for the comfort of the patient.

The Treatment of Tuberculosis of the Larynx and Prostate by the X-ray, High Frequency Currents and the Cooper Hewitt Light.—Dr. Sinclair Tousey read a paper with the above title. In regard to this sort of treatment for tuberculosis of the prostate he said he had not been able to find anything in medical literature. As regards the treatment of tuberculosis of the larynx by the Roentgen ray, Williams says: "The successful treatment of lupus by the X-rays should lead us to try them in laryngeal tuberculosis," and as long ago as 1897 Revillet reported their use in a case of acute pulmonary and laryngeal tuberculosis. Pusey and Cauldwell think they should be employed as an auxiliary to other treatment, and in their book is figured an X-ray tube for the treatment of the larynx. Having given a digest of the literature of X-ray treatment for pulmonary tuberculosis, Dr. Tousey stated that his own opinion at the present time was that judicious application of the X-ray or of the ultraviolet ray and high frequency currents is indicated in every case of tuberculosis. Treatment of tuberculosis of the larynx by the violet and ultraviolet rays, as produced by the electric arc light in its various forms, has been employed by Freudenthal in a number of cases with good results as regards pain and dysphagia, but no perceptible effect upon the tubercular infiltration or ulceration. He can see in the electric light only an adjuvant to the host of other remedies at our disposal, though an adjuvant that is of great assistance in some instances.

Dr. Tousey reported the case of a lady now under treatment for tuberculosis of the larynx. When first seen she had had throat trouble for three years and her weight had become reduced from 130 to 103 pounds. She was running a temperature of 102° F., and during the last four months had had profuse expectoration full of tubercle bacilli, and a visible tuberculous deposit in the larynx. She was constantly coughing and expectorating, and could scarcely speak above a whisper. There was considerable loss of strength, though she presented very little evidence of pulmonary trouble. His treatment was begun December 15, 1903, and consisted in exposure to the X-ray once in every four or five days, and exposure to the Cooper Hewitt light and application of high frequency currents once in each interval between the X-ray applications. In applying the X-ray he employed an 8-inch coil run by current from the street (110 volts direct current), using a liquid interrupter of his own devising. By it the current through the primary coil is interrupted at the rate of about ten thousand times a minute, and each such current passing through the primary coil induces a current of very high voltage in the secondary coil. From the two poles of the latter, wires pass to the two poles of the X-ray tube, the negative terminating in a concave mirror within the tube (the cathode), and the positive in a platinum disk in the center of the tube (the anode). In this case two different tubes were used; first, a Gundlach heavy anode tube of 60 cm. capacity, and later a Müller heavy anode tube of 50 cm. capacity. Both were provided with regulating devices, and the degree of vacuum was so adjusted as to give the greatest photochemical effect which could be combined with sufficient penetration to pass through the entire thickness of the chest. The distance from the nearest surface of the chest to the anode was about ten inches, and the time of exposure about five minutes in front and five minutes behind. The face and scalp were shielded by a sort of cap made of X-ray metal. Following the general exposure of the chest to the X-ray, a special application was made to the larynx by means of a tube made of lead glass opaque to the X-ray, with the exception of a cylindrical prolongation, into which the rays are directed from the anode and from the transparent end of which they emerge. The names of Cauldwell, Morton and Cossar have been associated with this tube, in which some trifling modifications have been made by Dr. Tousey. The tube is held close to the outside of the throat. The current employed is milder than that employed for the chest, and the exposure, which is maintained for only about three minutes, is distributed over different aspects of the larynx. The high frequency currents are obtained from the same 8-inch X-ray coil by means of the d'Arsonval transformer. A series of sparks passes across a spark-gap enclosed in a glass cylinder, and the vacuum electrode becomes filled with ten thousand waves a minute of ultraviolet and violet light passing into the surface of the body. A very large amount of ozone is also gen-

erated and carried into the body by the electric current, and this is regarded as an important feature of the application. The intensity is controlled by regulating the current in the X-ray coil and the length of the spark-gap, and the proper strength appears to be one devoid of prickling sensation, but sufficient to warm up the vacuum bulb when it is in contact with the skin. Dr. Tousey's vacuum electrodes have no wires. The lamp made for him by the Cooper Hewitt Company is actuated by the street current reduced by a rheostat to 5 ampères with 110 volts; this current passes through a vacuum tube 24 inches long and 1 inch in diameter, which contains vapor of mercury and at one end a certain amount of liquid mercury. The light given out has 400 candle power and its spectrum is almost pure violet, containing the chemical and life-giving properties of sunlight intensified about a hundred times. This light is applied for nearly fifteen minutes in front and for the same length of time behind the chest, from a distance of five or six inches.

The results of treatment have been as follows: Disappearance of expectoration (which took place in three weeks); very great improvement as to the voice; reduction of temperature to normal; marked gain in strength; and a gain in average weight of about two pounds. Considerable improvement has also occurred in the matter of swallowing, difficulty in regard to which appeared to be entirely psychic. As regards the local condition, before the treatment was commenced Dr. Richard Kalisch found an area of swelling and hyperemia below the left ventricular band, with a distinct line of abrasion, though hardly ulceration. He now finds the area of infiltration diminished and the abrasion healed, with a whitish appearance which may be due to cicatrization.

In tuberculosis of the prostate and bladder Dr. Tousey's treatment consists (1) in having the light from an ordinary X-ray tube shine obliquely downward through the lower portion of the abdomen and also occasionally through the perineum. (2) Alternating with the perineal application, a special X-ray tube is introduced into the rectum. This tube is made for the most part of lead glass opaque to the X-ray. It has an anodal disk; its cathode stream is directed down a cylindrical prolongation of the transparent glass, from which the X-ray emerges in all directions. This prolongation is cooled by a continuous current passing through a water-jacket. The application lasts for only a couple of minutes. (3) The application of high frequency currents over the lower portion of the abdomen, and also in the rectum on occasions when the intrarectal X-ray tube is not employed. For the intrarectal application of high frequency currents a special vacuum electrode is employed in which the tube is insulated, except for its distal two or three inches, by a separate external cylinder of glass. The application lasts five minutes.

Tuberculosis of the Bladder and Prostate.—A patient now under treatment is Mr. M., aged thirty-one years, who for several years has had this affection. A year ago he was treated with the X-ray, the application being made daily by allowing the light to shine upon the lower part of the abdomen while the patient stood up in front of the tube; also by the application of vacuum electrodes connected directly with the X-ray coil without the d'Arsonval transformer. Following this treatment, several enormous pus sacs formed and after causing months of suffering emptied into the bladder. When he came to Dr. Tousey, December 23, 1903, he was urinating 25 to 30 times a day, the urine looked like a mixture of blood and pus, and microscopical examination showed the presence of tubercle bacilli. On rectal examination the prostate was found to be moderately enlarged and tender. He has been treated twice a week, and irrigations have been continued. There were at first considerable pain and irritation in the urethra, and scales could be washed out of it. This condition has been relieved by X-ray applications, the penis being held up against the abdomen during the treatment. The patient's weight has increased from 147 to 152 pounds, there has been no formation of pus sacs, as before, and his comfort and strength have uninterruptedly improved. The frequency of micturition has markedly decreased, so that at times he is able to go five hours without urinating. The urine is much clearer, and no visible blood has been present in it for two months. The microscopical examinations showed at first an increasing and lately a rapidly decreasing number of tubercle bacilli. The last examination, a day or two since, shows only an occasional bacillus.

Dr. Tousey then gave a demonstration of the special apparatus described in the paper and also of a method of skiagraphy in which the picture is produced directly upon sensitized paper and may be developed in any dimly lighted room. A photographic dark room is not required, and the whole process occupies but a few minutes.

Unfortunate Results from X-ray Treatment.—Dr. H. Holbrook Curtis had seen very unfortunate results from X-ray treatment in three cases of laryngeal tuberculosis. The application, he believed, was apt to be followed by bleeding. He had supposed that high frequency currents produce effects opposite in character to those of the X-ray, and he could not well understand why they should both be used in the same patient.

Encouraging Results from High Frequency Currents.—Dr. W. Freudenthal said he had used the X-ray in a few cases, but did not feel that he had had sufficient experience to form a positive opinion in regard to its effects. He did not introduce a tube into the patient's mouth. In employing high frequency currents, however, he had introduced the electrode directly into the larynx, and he had had some very encouraging results from the method. The incipient cases of tuberculosis got better under it. In the secondary and tertiary stages of the disease he had been able to abolish pain to a large extent, and this was undoubtedly a great item. There were cases in which the affection improved in the lungs, but did not in the larynx. The violet rays did not seem to penetrate the cartilage, but a method had now been devised by which the red and yellow rays could be rendered just as efficient as the violet.

Failures Much More Numerous Than Successes.—Dr. Albert C. Geyser said it was proper that in his digest of the literature of the treatment of pulmonary tuberculosis by the X-ray Dr. Tousey should have given the failures, as well as the successes. It was noticeable, however, that the failures were far in excess. In a large number of instances it did not seem to make any difference what treatment was employed. If patients were inspired with a feeling of hopefulness they improved for a time under any kind of treatment. Then came the reaction, and they began to go down-hill. He himself had treated five cases of tuberculosis of the larynx with the X-ray. Of these three died, one grew positively worse, and one had disappeared. He did not think that any effect could be got from applications external to the larynx. The high frequency currents were stimulating. Their effects were exactly opposite to those of X-rays, and, like Dr. Curtis, he was somewhat at a loss to understand why both these should be employed on the same patient. He trusted sincerely, however, that Dr. Tousey, with his three kinds of light, would have better success than some other observers had had.

Tuberculosis of the Urinary Tract.—Dr. H. G. Spooner said that the action of high frequency currents and of the X-ray on tubercle bacilli was essentially the same. The bacilli first rapidly increase in number and show a tendency to form clumps, then they gradually diminish and become paler in color. The general improvement of the cells of the body probably makes them more resistant to the invasion of the tubercle bacilli; but whether the vitality of the bacilli is lowered or whether the raising of the vitality of the cells, or a combination of both is at work, we do not know. Now, inasmuch as fresh air and an outdoor life have proved of signal service in many of the cases of urinary tuberculosis, it would seem to be but reasonable that the X-rays and high frequency currents, by stimulating the cells of the entire body, should have a sphere of usefulness in genito-urinary tuberculosis, particularly of the prostate, as an aid to hygiene, diet, etc.

High Frequency Currents Probably More Efficient Than the X-ray.—Dr. Joseph W. Gleitsmann said that he had not as yet formed a decided opinion in regard to the relative value of the different lights. He could say, however, that the X-rays had not given the satisfaction which he had expected. He had seen better results from high frequency currents locally applied. In conditions other than laryngeal tuberculosis, such as glandular swellings of the neck, this form of electricity appeared to be quite beneficial. In tuberculosis he had met with no results to speak of.

BOOK REVIEWS.

A System of Practical Surgery. By Prof. E. von Bergmann, M.D., Prof. P. von Bruns, M.D., and Prof. J. von Mikulicz, M.D. Volume I. Translated and Edited by William T. Bull, M.D., Professor of Surgery, College of Physicians and Surgeons, Columbia University, New York, and Walton Martin, M.D., Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York. Surgery of the Head. Lea Brothers & Co., New York and Philadelphia.

The appearance of this work in English has been looked for with much interest and now that the first volume is in our hands we shall await the others with a still greater degree of pleasurable anticipation. The character of the original and the names of the American editors are such as to justify the most extravagant expectations and yet it is no exaggeration to say that these have been more than realized. There is a distinct gap in our surgical literature, which this work seems well adapted to fill, for, while there is an abundance of excellent surgical treatises of the less comprehensive type, no American system of really pretentious scope has appeared of recent years. In its German form the present work achieved such a popularity that the earlier volumes were appearing in a second edition before the later ones had all been issued, and translations have already been made into several other languages. The names of v. Bergmann, v. Bruns, and v. Mikulicz are such as to attract attention singly, and in combination they form an editorial trinity hardly to be excelled among continental surgeons. Given such a groundwork as was afforded by the second edition of their production, it is not surprising that the American editors with their collaborators should have succeeded in bringing forward a work which will probably remain for years the court of last resort in questions of surgical theory or practice. The German text has in many instances been enriched by descriptions of improvements in technic devised by American surgeons, and also by increasing the number of illustrations which almost without exception are both interesting and useful.

This volume on the surgery of the head is the work of eight authors, including such prominent men as v. Bergmann, Krause, Krönlein, Kümmel and Schlatter. Separate sections are devoted to the skull and its contents, the ear, the face, including plastic operations, the neuralgias of the head, the salivary glands, the jaw, the nose, the mouth and the pharynx. This purely regional arrangement has made appropriate assignment of the material easy and each section is the work of a man whose name has become prominent in respect to that particular field. Thus the monograph on the injuries and diseases of the skull, as written by v. Bergmann, stands out with an authoritativeness no less celebrated a writer could impress upon it and Krause's discussion of the cranial neuralgias possesses unequaled interest and value.

With a work laid out on such broad lines and covering the field with such wealth of detail, it is impossible to single out separate topics for special discussion. In every section which the reviewer has perused the impression has been one of extreme thoroughness and reliability combined with much attention to the practical application of the principles laid down. The translation has been well carried out and an agreeable smoothly following text produced. In every respect the work seems destined to secure for itself a place among the most important contributions to the study and practice of surgery and will no doubt command the most widespread attention.

Le Malattie dei Paesi Caldi Loro Profilassi et Igiene (Diseases of Warm Countries, their Prophylaxis and Hygiene). Ulrico Hoepli, Milan.

This little volume contains in brief space a wonderful amount of observation with regard to the diseases of warm countries, their prophylaxis and hygiene. It is of all the more interest now, since our own possessions in the American tropics as well as in the East and the work on the Panama Canal are likely to bring the physicians of our larger seaboard towns in touch with many more of the specific diseases of warm countries than was the case before. The volume also contains an excellent account of the various cutaneous affections due to parasites that inhabit the various warm countries.

There is an appendix to the little volume regarding life in Brazil that will be of special value to those contemplating a residence in that country. This gives details not only with regard to the special diseases of Brazil but also its fruits and plants as well as its animal parasites, its snakes, especially the poisonous reptiles, its spices, and so forth, which are the result evidently of information gathered during travels in that country.

The general impression gathered from the book is that the diseases of hot countries are by no means so frequent or inevitable by the foreign-born resident as has been thought and that the removal to a tropical climate is by no means necessarily the almost fatal step it has been considered. The white race is evidently destined to play a much more important rôle in the tropics than has hitherto been imagined.

La Rachitide, E Le deformita da essa prodotte—(Rachitis and the Deformities Produced by It). By P. Mancini, M.D., and Manuele Hoepli. Ulrico Hoepli, Milan.

This little volume, with some 116 illustrations in the text, contains an excellent review of our present knowledge to date of this serious bone condition, which has

so long been a source of interest to physicians and pathologists, and yet has, in spite of all the study devoted to it, retained something of the mystery it had at the very beginning.

The chapters on prophylaxis and cure occupy nearly one-half the book and contain many valuable suggestions as regards diet, drug treatment, exercises of various kinds, so as to prevent misdevelopments, and finally, orthopedic treatment. The whole is evidently written by a man who has been deeply and practically interested in the subject about which he writes and whose experience cannot help but be of value to others. It is very evident that this little series of manuals is going to be of great suggestive value to all those who, outside of Italy, can read Italian, as well as to Italian physicians themselves.

Elettricita Medica (Medical Electricity). By A. D. Bocciardo, M.D. Ulrico Hoepli, Milan.

This little volume, which forms another of the series of the Hoepli Manuals, contains a better résumé in a shorter space of modern electricity and its application to medicine than anything the reviewer has hitherto seen. Writers on the subject in English would certainly do well to consult this unpretentious manual when compiling or revising their books. It is well illustrated and is thoroughly up to date. Those interested especially in the subjects it treats, which include the use of the Roentgen rays, phototherapy, and radiotherapy will find it to their advantage to consult it because of its suggestive practicalness.

A Handbook of Ophthalmic Science. By Henry E. Juler, F.R.C.S., Ophthalmic Surgeon to St. Mary's Hospital, Consulting Surgeon to the Royal Westminster Ophthalmological Hospital, Consulting Ophthalmological Surgeon to the London Locke Hospitals. With illustrations. Third edition. Revised and enlarged. Lea Brothers & Company, New York and Philadelphia.

This excellent book appears in the third edition with few changes, and deserves the consideration it has received in the past. It expresses in great part the personal attitude of its author, and in this respect is perhaps more interesting than many books which are more modern in attitude, and more elaborate in detail. The treatment of the subject is conservative and commands respect, although in some instances the point of view is somewhat different from our own. Very little attention is given to methods which have not been thoroughly established. The book is, therefore, a safe guide for the student. But it must not be thought that the most recent steps in ophthalmology have been ignored. The operative treatment of myopia, and the operation of sympathectomy for glaucoma are mentioned. It is truly stated of the latter that it is doubtful whether a favorable result is permanent, but the statement that the operation is accompanied by severe constitutional symptoms cannot be accepted, if the operation is properly done. This operation is still *sub judice*, and the discussion should not be confused by a mistaken idea as to its apparent gravity. The chapters on cataract and its treatment and on refraction are commendable, although one might differ with regard to the value of tests for astigmatism. Very few, we fancy, would give first place to the use of the stenopeic slit, but the fact that it is overlooked in other books makes its prominence here of interest.

Retinoscopy is given sufficient consideration.

The chapter on the ocular muscles is adequate, except the brief consideration of heterophoria, which, to many of our modern specialists, may seem incomplete, but perhaps that is an error on the safe side.

The illustrations are numerous, and for the most part excellent. The colored plates, 17 in number, are a little hard and crude in color, but they are quite as accurate and helpful as others in which the printing has been more successful. The diagrams are clear and decidedly helpful. There are appendices giving formulæ, visual tests and numerous semidiagrammatic plates illustrating the normal and pathological histology of the eye. The index is excellent. The work of the publishers leaves something to be desired, the binding is rather weak. The typography, however, is good, and it is a pleasure to note the use of paper which is slightly cream in tone, and has a dull surface.

A Manual of Psychology. By G. F. Stout, M.A.Camb, M.A.Oxon., LL.D., Aberdeen, Wilde Reader in Mental Philosophy in the University of Oxford; Examiner at London University; Editor of *Mind;* etc. Hinds & Noble, New York.

As might well have been expected, the editor of *Mind* has produced an excellent manual of psychology. With the thoroughness of an English writer he has combined something of the popular note in scientific writing which is so much more characteristic of American writers on scientific subjects. The book is likely to be of interest to physicians, because Dr. Stout is convinced that the study of psychology is of no use to the student unless he is able to live himself into psychological problems so as to acquire a real power of thinking for himself on psychological topics. For this purpose, cut and dried statements and the skimming of important questions are of no avail.

The reviewer notes some of the passages which in reading have particularly drawn his attention to the value of the book for physicians. In the chapter on Emotions in the discussion of unfamiliarity and the effects of fright there is the story of the dog who was frightened into a sort of epileptic fit by a bone being drawn across the floor by a thread which he did not see. The chapter on Memory contains a number of passages that are likely to be suggestive to physicians. The same thing may be said with regard to the chapter on Voluntary Decision, the reading of which makes many of the peculiar phases of the doubting mania or *folie de doute* of the French, more clear. In general, the book contains an excellent résumé of modern psychology that cannot help but be useful to those interested in psychological problems, either from the educational, the social or the humanitarian standpoint.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear:*

Pain and Its Indications. By Dr. E. C. Hill. 12mo, 328 pages. G. P. Engelhard & Co., Chicago.

Medical News Pocket Formulary. 12mo, 287 pages. Lea Brothers & Co., New York and Philadelphia.

SOME CONSIDERATIONS ON INFECTION AND IMMUNITY.[1]

BY THOMAS E. SATTERTHWAITE, M.D.,
OF NEW YORK.

THERE are certain epochs in the study of vexed questions, when a knowledge of their *status praesens* is desirable. We have now reached such a period, with reference to the somewhat obscure topics of infection and immunity. It is the purpose of this paper to supply this information, so far as a brief statement of facts, stripped of unnecessary technicalities, makes it possible.

When Pollender,[2] about the middle of the last century discovered the bacillus of anthrax, the first notable impulse was given to the study of infection. A little later Davaine produced the artificial disease in animals by injecting blood containing these bacilli. Pasteur in his turn cultivated the bacilli in nutrient fluids and produced "pure cultures." Later, Koch separated different kinds of bacteria by "plate cultures," and "cultures in solid media." Novel methods of staining and the use of special objectives further aided in differentiating one species from another. This brief outline of facts introduces us to the present bacteriological aspect of infection.

So far as immunity is concerned, after it had been secured from smallpox by vaccination, the next step was made by Pasteur, working on the assumption that a mild form of the disease might produce exemption. He "attenuated" the virus in several ways, and his methods for inoculating cattle and sheep against anthrax have been widely used and highly approved. The discovery of the antitoxins, however, we owe to Salmon and Smith of this country. But the method of preparing them is generally attributed to Behring. These discoveries have been of inestimable value in the saving of life. For experimentation has shown that infection is caused by microscopic vegetable or animal life, or their products.

In diphtheria and tetanus the infecting agents are referable to microorganisms of a vegetable character. Malaria, amebic dysentery, the "Texas disease" and "surra" in horses and mules however, are due to protozoa, in other words to microscopic animals; while there is always a possibility that yellow fever, scarlet fever and smallpox may be found to be caused by allied animal organisms, though as yet satisfactory proof is lacking. But so far as we now know, bacteria are the chief causes of disease, and the infecting bodies in tuberculosis, typhoid, glanders, gonorrhea, anthrax, tetanus, bubonic plague, suppuration, erysipelas, lobar pneumonia, influenza, diphtheria, ordinary dysentery, cholera and relapsing fever are believed to have been discovered, although they cannot all stand the test of Koch's well-known law, which is

1. That the microorganisms must be found invariably in a given disease and in no other, their numbers and distribution conforming to the lesions of the disease.

2. That the organisms obtained from lesions of the disease must be capable of reproduction in pure cultures.

3. That these cultivated germs must be capable of producing the disease if inoculated on a susceptible animal.

4. That these artificial lesions contain the specific organisms.

Of the list thus given cultures of the bacteria of bubonic plague and glanders have on several occasions communicated these diseases to laboratory workers, and sometimes have caused death. In others such as leprosy, there is doubt whether the bacillus has been successfully cultivated, certainly, inoculation experiments have yielded uncertain results; while erysipelas appears to have no specific bacterium, and to be due rather to the *Streptococcus pyogenes,* one of the pus-producing bacteria.

There is no doubt that the requirements of Koch's law are severe. It is one thing to see a successful development of the inoculated culture within the body of an animal, and another to reproduce the disease with its clinical signs. This latter requirement has been the great stumbling block for laboratory workers.

There is also a strong presumption that the infecting agent is bacterial in syphilis, mumps, measles, whooping cough, typhus, hydrophobia, dengue, acute inflammatory rheumatism and beriberi, but the proof is still lacking just as in yellow fever, scarlet fever and smallpox.

Possibly some of these organisms are so minute, that they cannot be differentiated by our present microscopes. Nor has the last word been said as to the morphology of the bacteria with which we have to do.

But there is another class of microcytes that are concerned in causing disease. These we call fungi. They are usually classed among the mold or yeast fungi. Of these a conspicuous example is actinomycosis, which causes the "big head" of cattle, and occasionally occurs in the human subject. Another is the *Leptothrix buccalis,* which causes the gangrenous inflammation of the mouth called "noma."

The *Aspergillus niger* may also produce a disease of the external ear, or complicate a bronchial pneumonia, in which latter case it will be a secondary infection. These microcytes, which

[1] Introductory to a Symposium on "The Combat with Infection," American Therapeutic Society, June 4, 1904.
[2] As early as 1849.

like the *Aspergillus* live on dead matter, are called saprophytes, and they are classed as facultative, if they have the inherent power of infection independent of contamination from sources outside of the body.

Evidently then, according to our present information there are three sources of infection. The most common appear to be bacteria, less often fungi; and least of all, protozoa, though the latter are certainly assuming a greater numerical importance.

Allusion has been made to the fact that bacteria may not cause infection directly. This discovery was due to the study of the *bacterial* poisons called *ptomaines,* which could be easily isolated. For a ptomaine may be regarded as an organic chemical compound, toxic in character, formed by the action of bacteria on nitrogenous matter.

Now the poisonous effects produced by the inoculation of some of these ptomaines on animals led to the supposition that analogous substances formed by the specific bacteria of infective diseases *might* account for their characteristic symptoms. But research has not determined the intimate nature of these bacterial products. We know they are poisonous and call them *toxins,* but their composition is unknown; in fact it has been found impossible to isolate them so completely as to establish their chemical characters. And yet they have been obtained from the bacteria, not only of diphtheria and tetanus, but of other diseases.

There is also some evidence to indicate that other specific bacteria elaborate poisonous products. In fact bacteria as a rule generate special poisons, though in typhoid fever and in cholera certainly, the poisons remain for the most part inside the bacterial bodies.

From our present standpoint, the question of incubation offers few difficulties. At the beginning of an infective disease, the infecting bacteria are comparatively few in number, and their toxins small in quantity. But both develop proportionately, the elevation of temperature and constitutional symptoms keeping pace with their development. When enough poison has been generated, the disease manifests itself by characteristic signs. The time required for this purpose will depend on the quantity or virulence of the initial dose, and the resistance offered in the body.

These circumstances may account for the variability of the duration of incubation. That it is even tolerably uniform in the various infections is quite remarkable.

The term *contagion,* in the narrow sense, suggests that it should be limited to diseases communicated by direct animal contact. But even in the most virulent of them, such as gonorrhea, the contact may be mediate, rather than immediate, contaminated objects, such as soiled linen, serving as vehicles for spreading the disease. In yellow fever, also, the *Culex fasciata* appears to carry the poison, while the tsetse fly of the East, infected with the *Trypanosoma* inoculates horses and other animals, and even man occasionally, producing the fatal "surra." Rats, and probably flies, ants and fleas are also the intermediate hosts of the plague germ. Evidently then, in these most characteristic contagious diseases, there is infection, and therefore they are infective. On the other hand, infective diseases may not be contagious. Epidemic cerebrospinal meningitis is an example. It is infective, but not contagious in the ordinary sense, that is, it does not appear to be carried from person to person.

Infection accordingly may be mediate or intermediate, direct or indirect. Anthrax, typhoid, cholera and diphtheria can be propagated in either way. For typhoid and cholera can be transmitted through the media of water, in which they can live, if only there is a very little albumin; or directly from the excreta. Diphtheria can be communicated through the medium of milk, or by contact with an infected person. The possibility must be borne in mind, however, that these and the bacilli of typhoid may have a mycelial growth like the fungi; even that sometimes they may be facultative saprophytes, *i.e.*, that they can develop *de novo* in suitable dead material. On this point however, it is true, the evidence is unsatisfactory. In some affections, like tetanus and diphtheria the pathogenic bacteria have only a local manifestation; in others like anthrax, they may infect the blood throughout the system.

Obviously, from a therapeutic point of view there is a vast difference between the two. But these conditions are not constant. For example, in the experimental anthrax of guinea-pigs the disease is apt to be systemic, while in mankind it is apt to be local. A mouse inoculated with anthrax in the end of his tail, may die in less than a day, while an individual whose hands have been poisoned by handling anthrax hides, may have only a comparatively mild local affection.

In fact, the behavior of any animal toward an infection varies according to the species, the individual, or circumstances. The frog is refractory to anthrax under normal conditions. The resistance of the guinea-pig to the diphtheritic poison may be acquired by successful inoculations; so that finally a dose that would be fatal under ordinary circumstances may cause no reaction at all. In the discussion of this subject also, it should be borne in mind that there is apt to be a wide difference between the human disease and the experimental of animals, both as to symptoms and lesions. If a rabbit is inoculated with a bit of diphtheritic membrane, it will usually sicken or often die, but no membrane will appear on any mucous surface. In seventy inoculations[1] practised on rabbits, by Dr. Edward Curtis and myself, with known diphtheritic poison, in the aqueous infusions of pure membranes (plain, boiled and unfiltered), porous clay filtrates, putrid infusions (plain and boiled), and others intermixed with salicylic acid, in no in-

[1] "Pathology of Diphtheria." N. Y. Bull. of the Board of Health, Feb., 1877.

stance was there any diphtheritic membrane found on a mucous membrane of these animals, though autopsies were made on twenty-five of them, usually with great care. Nor did paralysis occur in any one of them.

It is said, however, that if the vaginal mucous membrane of young guinea-pigs is inoculated with diphtheria bacilli, a pseudomembrane will appear there; and yet it is to be remembered that a pseudomembrane apparently similar sometimes occurs independently of diphtheria, when mucous membranes are inflamed. In tetanus, however, there is a marked resemblance between the human disease and the artificial of animals, even to the character of the spasms. On the other hand, in diseases such as anthrax, glanders, and foot and mouth disease, which occur both in men and animals, there is sometimes an extraordinary similarity in the symptoms; but they are never alike.

It can certainly be said of the lesions of tuberculosis that they are unlike in men and animals. As long ago as 1882[1] I called attention to this point, for in investigating the pathological lesions of pleuropneumonia in cattle, I had the opportunity of seeing many instances of bovine tuberculosis, with which pleuropneumonia was sometimes confounded, and I epitomized the differences at that time, stating that in man the tubercle tends to become caseous: in cattle cretaceous. Besides, the ulcers and cavities of advanced human phthisis occur rarely, if at all, in cattle. The little centers of disease grow by the deposit of cretaceous matter in concentric layers until the pulmonary lobule is distended to many times its normal size, eventually forming a yellow tumor of stony hardness. The interlobular tissue also is filled with little tumors, usually pedunculated, that vary much in size. The visceral and parietal layers of the pleuræ are also covered with similar tumors, which form grape-like clusters, known as "grapes" or "angleberries." In 1896 Theobald Smith[2] noted also a difference in the two bacilli. That the pathological lesions of bovine tuberculosis are quite unlike those of the human variety is therefore apparent. These are but examples of the differences between the diseases of mankind and the lower animals, called by the same name.

In pursuing this matter further we find that susceptibility is a relative, instead of an absolute term. It may mean merely that a small rather than a large dose is necessary to produce infection. Susceptibility may be inherent in an individual, in races, or in genera. We all know that some persons will not contract malarial poisoning and that colored people are refractory to yellow fever. But pigs are not susceptible to tuberculosis, while the guinea-pig is easily infected. In the same way immunity is a relative rather than an abstract term.

Three varieties of susceptibility are recognized, a natural, acquired and an inherited. The natural susceptibility of some animals is very great. For instance, mice and guinea-pigs are peculiarly susceptible to anthrax poison. We also know from experiments that certain persons will contract almost any infective disease to which they are exposed, while others under similar conditions will escape. This disposition may be inherited in a given case, though it may not be natural for the species. Some of the protective influences we know. Age is one. During the first years of life there is little disposition to infection, but from that period on until puberty the tendency increases gradually. As old age approaches, there is a somewhat progressively decreasing disposition to infection. Similar conditions are observed in the lower animals. In animals deprived of food or drink the susceptibility is increased. Improper or unaccustomed food, sudden changes of temperature, shock, spasms, fatigue, exhaustion, worry, are closely related to the causal production of infection. The final disease, or, as it is now called, the *terminal* affection, so commonly the cause of death in chronic non-infective diseases, is apt from these causes to be infective, and for this reason. Assuming in a given case tuberculosis to be the terminal affection, it may have remained latent for an indefinite term, until the shock of an operation, exhaustion following parturition, or some wasting or chronic disease has broken down the individual's susceptibility, when the tuberculosis takes on an acute form and carries him off.

I have now to speak of acquired and inherited immunity. There are two forms of acquired immunity, the active and the passive; and they are of great interest to us of the present time. Active immunity is best described by what it accomplishes. For example, the attack of an infective disease produces active immunity for a variable period. So do small doses of virulent cultures; large doses of cultures attenuated in various ways; injections of bacterial products as employed by Haffkine for prophylactics against plague; and injections of the sterilized products of the bacillus. This latter method has been employed with some success in tetanus and diphtheria.

At first small doses of the toxin are used, and the amount is gradually increased until immunity is accomplished. An animal may be so immunized that it will not react to a dose 100 times the amount necessary to kill the animal before inoculation began.

This method is used in conjunction with the inoculation of living and virulent cultures in the preparation of the antidiphtheritic sera taken from horses.

Passive immunity is produced by antitoxins. Salmon and Smith of Washington were the pioneers in this movement,[1] as I have already said. Experimenting on pigeons with the filtrates from cultures containing the products of the hog cholera bacillus, they found that

[1] "Considerations on the Origin and Natural History of Tuberculosis." Medical Record, October 28, 1882.
[2] Journal of Experimental Medicine, Vol. III, p. 451.

[1] Smith, Procedures of the Biol. Soc. of Washington, Vol. III p. 29, 1884–1886.

pigeons were made immune to the bacillus which produced the disease in ordinary pigeons. Behring followed by devising a plan for preparing the antitoxin. The bacilli are first cultivated in bouillon, and then the cultures are freed from bacilli by filtration. The filtrate containing the toxin is then injected into horses, in successively increasing doses. After large quantities of the serum have been injected, the horse, becomes immunized. In the serum of his blood is the antitoxin. Of course some modifications of this method are in use, but in the main it is carried out in the manner stated.

In passive immunity the individual inoculated with the antitoxin shares the immunity *passively* with the animal from whom the antitoxin is drawn. It is the condition produced by serum therapy. The antitoxin is both prophylactic and curative, but the dose required for a cure is much larger than for prevention. Passive immunity can be produced quickly; active immunity requires time, but has a more enduring quality than the passive form.

Inherited susceptibility is perfectly comprehensible, just as any other quality transmitted from a parent. Inherited immunity has been shown experimentally in anthrax and tetanus. On the supposition that the mother has been actively or passively immunized, the offspring may partake of her immunity; or enjoy a natural immunity handed down by either parent.

We are at all times beset by infective bacteria. They are in the air we breathe, the water we drink and the food we eat, but if the amount is *subminimal,* that is, below the toxic dose, we are not poisoned. If the dose is maximal, infection may easily take place. An instance of this kind recently came under my observation. A father and mother with four children living in a tenement house, in four small rooms, with only two windows, were all prostated at one time by epidemic influenza, while other families in the tenement were not affected. The poison in this case was present in maximal quantities. The site of the inoculation is also a controlling factor. Some parts are less resistant than others. A part of the body that is in a normal condition may be successfully inoculated, while a similar part in a state of inflammation may be refractory. We have already seen that the virulence of a pathogenic organism may be raised or lowered by artificial means. We may produce a pure culture or attenuate it.

Specific infection, however, is apparently diminished or intensified by microorganisms other than the pathogenetic ones.

Thus tetanus is possibly dependent to some extent on the microorganisms associated with the specific. On the other hand, if the bacillus of anthrax is inoculated together with the bacillus of erysipelas, the attacks of anthrax will be mild as compared with an attack where the anthrax bacillus alone had been inoculated. So in diphtheria, the association of staphylococci or streptococci with the bacilli of diphtheria is apt to modify the course of the disease. These are examples of what is known as *mixed infection.* To render an animal immune there is another method besides that of neutralizing the toxin by antitoxin. It is by the use of *bactericides.* When microorganisms alone are used for producing immunity, the serum develops marked antibacterial powers, while it has little or no effect on the toxins elaborated. On the other hand when the filtered cultures (toxins) are used, the serum develops both antitoxic and bacteriolytic properties.[1] It is apparent therefore that the sera prepared by these two methods are not identical. These principles are recognized in the manufacture of the various specific sera, such as the antidiphtheritic serum, antiplague serum, etc., and both bacteria and their toxins are, as a matter of routine, injected into the donating animal, though in antivenin (snake poison), bacteria are obviously not necessary. And so most sera used in the treatment of disease have both antitoxic and antibacterial powers. This is important, for as a *curative* remedy, an attack is made not only on the bacteria that make the toxins, but on the toxins which produce the disease. But from a prophylactic point of view, it is sufficient that a serum has *bactericidal* properties.

A curative serum, therefore, is necessarily a protective. As there is a great variation in the amount of serum required in a given case, it has been necessary to standardize the serum to make it effective. The method of Ehrlich is now generally used. This is his method—First of all the least amount of diphtheritic toxin which is requisite to kill a guinea-pig (weighing say 250 to 300 grams) in 3 to 5 days is determined. Then an estimate is made of the exact amount of antidiphtheritic serum that is required to neutralize 100 of the above toxins. This constitutes the *unit.* Now, this unit may vary in size, but the more potent the serum the less the quantity required in an injection. Therefore to make this quantity as small as possible, or, in other words, to diminish the size of the units, the antitoxic value of the serum is raised as far as practicable by injecting the horse as many times as possible.

As already intimated the animal body has the power to produce certain substances that will defend it against all sorts of alien cells and their products. But the nature of these substances is unknown. And yet we know that they are able to neutralize poisons, agglutinate cells, cause precipitation and coagulation, etc. These antibodies are classed as antitoxins, agglutinates, precipitates, coagulins, etc. Those that destroy cells are classed as cytolysins, and this includes the bacteriolysins (bactericides), and the hemolysins, which destroy the red blood corpuscles. There are also a number of other destructive substances known generically as lysins, but having specific powers. Such anti-substances are produced by

[1] In bacteriolysis the bacteria are dissolved, in hemolysis the red blood corpuscles are dissolved. In leucolysis, the white corpuscles are dissolved.

the repeated inoculations of an animal with small doses of the substances against which it is desired to obtain the anti-substance. By this process, however, more than one anti-body can be formed. For example, repeated inoculations of a rabbit with typhoid bacilli cause the rabbit's serum to have not only bacteriolytic, but also agglutinic properties. The substance that causes agglutination was discovered by Pfeiffer[1] who found that if mobile cholera organisms were introduced into the peritoneal cavity of guinea-pigs immunized against cholera they would become motionless, adhere together ("clump"), become granular and eventually disappear; but he also found that similar "clumpings" would take place when typhoid bacilli were injected into an animal immunized against typhoid fever. Bordet[2] simplified the procedure when he discovered that "clumping" could be produced in a test tube, if the immunized serum were added to a broth culture of the microorganism. In the test tube, however, no granules were found in the bacteria, nor did they disappear. In fact, after some hours, usually about twenty-four, the clumps broke down, the bacteria resumed their activity and began to multiply. In Pfeiffer's method, therefore, the serum is agglutinative, and also bacteriolytic; in Bordet's it is only agglutinative.

The discovery of "clumping" or agglutination has been of the greatest value, and forms the basis of the Widal test in typhoid fever. It is true it may be found, to some extent, in normal sera, and other organisms besides those of Asiatic cholera and typhoid fever will agglutinate, but the phenomenon is so imperfectly marked that it has not been regarded as seriously affecting the value of the Widal test.

The Widal reaction, as is well known, is as follows: if equal parts of a serum and of a solution containing typhoid bacilli are mixed together, it will be found in a large number of instances that agglutination takes place, no matter what kind of serum is used, and this agglutination will continue for hours. But if the serum is greatly diluted and the time limit fixed at an hour, the typhoid bacilli will be agglutinated only by serum derived from an individual in whom typhoid bacilli have been growing.

In the Widal method, serum from the suspected patient is mixed in various degrees of dilution with a cultivation of proved typhoid bacilli, and the time limit is fixed at one hour. If agglutination is marked within that time in a dilution of 1 to 50 or more, the reaction is said to be present. The greater the dilution the serum will stand before its agglutinating powers are lost, the greater the certainty of typhoid fever. In human patients agglutination will often occur when the dilution is 1 to 100 of serum.

But after all, this determination of the specific character of a disease by the agglutinating process has its limits.

For example, there are some sorts of the colon bacillus that will agglutinate in high dilutions. Blood serum also in jaundice often agglutinates typhoid bacilli in high dilutions, but this may be explained from the fact that cholangitis is often due to typhoid bacilli. Again, the reaction to this test may continue for many years. These facts should be taken into consideration in our valuation of the Widal test.

The following theories of immunity are the most important,—*The Exhaustion Theory*[1] holds that when an infective disease has exhausted the "pabulum" on which the disease feeds, there is immunity.

The Retention Theory holds that acquired immunity is due to storage in the body of bacterial products which prevent the growth of that variety of bacteria that produced them.

The Phagocytic Theory of Metchnikoff was and is based on the theory that the cells of the animal kingdom protect themselves from invading cells by devouring them (phagocytosis). Accordingly immunity from a disease means that the phagocytes of the infected animal are able to devour the attacking bacteria. Susceptibility implies that the invading bacteria are able to overcome the phagocytes. Phagocytosis is really a phenomenon of the animal kingdom that is generally recognized, hence analogically there is a basis for it. According to Metchnikoff the leucocytes and endothelial cells are to be classed among the phagocytes. This theory has been successfully attacked, however. In the first place, in many infective diseases, bacteria are not eaten up. Indeed, bacteria may, as in gonorrhea, survive the cells that have swallowed them. In fact the cells are often attacked by bacteria, rather than the converse. Besides, the so-called phagocytes may actually help to spread the disease by carrying the bacteria to remote parts of the body. This theory has, therefore, no universal application, though partly true.

The Humoral Theory propounded by Fodor[2] holds that bactericidal properties exist in many fresh specimens of blood serum, and that the anti-bodies,[3] known also as defensive substances or alexins are of a chemical nature; and that they induce immunity. There is no proof, however, that they have a chemical nature. Besides it is pretty certain that cells have something to do with infection.

The *Cellulo-Humoral Theory* has aimed to unite the theories of the phagocytic and the humoral schools, in other words, the French and the German.

Both cells and fluids are concerned in natural and artificial immunity. Immunity is due, not only to substances related to the blood of the immun-

[1] Theories are stated as they were originally propounded.
[2] Fodor, Deutsch. med. Woch., 1887, p. 745.
[3] According to Buchner and Hankin these anti-substances are proteids. They are called sozins, if present in the normal serum; phylaxins, if the result of immunization. Sozins destroy both blood cells and bacteria, and are themselves destroyed by a temp. of 131° F. If they successfully oppose the bacteria, they are called mycosozins, if the toxins, they are called toxo-sozins. The phylaxins, or true antitoxins destroy neither blood cells nor bacteria, and retain their properties after exposure to 176° F. If the true antitoxin counteract the bacteria, they are called mycophylaxins; if the toxins, they are called toxophylaxins.

ized animal, but also to its tissues and juices. These substances are formed by the cells of the body during exposure to the toxins, and for a while afterward. But they are not formed by any one variety of cell, but more or less by all the cells of the body.

These protective substances meet and resist the bacteria and their toxins. Stimulated by the bacteria, they produce anti-bacterial substances, while the toxins stimulate the same cells to produce antitoxins.

Ehrlich's Side-Chain Theory was promulgated in 1897, and is the most recent of the methods by which an effort is made to utilize established facts to explain the process. The fundamental idea of Ehrlich is that the protoplasmic body, or the cell (in other words) is a complex structure, consisting of a central body with lateral processes (side chains he calls them), that are capable of combining with or being replaced by other bodies.

This idea is based on an analogous condition recognized in organic chemistry, which is used to explain the relations of iso-meric compounds. Ehrlich holds that the cell (protoplasmic body) is capable of forming a vast number of these processes or side chains, and that a separate process can be formed for every blood or cell poison that exists. These processes he calls *receptors*. Each receptor is capable of dealing with a single body, whatever its character or chemical composition, whether solid or fluid; but it has a double function, one of attaching itself to a protoplasmic molecule and the other of inoculating the cell.

The fixing agent is called the *Haptophor* (anchoring agent); the inoculating, the *Toxiphor*.

If the poison is very virulent the cell is destroyed, and if many cells are damaged, the animal may die. If however, the animal survives, the damage done to the cell process (receptor) calls for a new formation of processes similar to those that have been injured. Now, the reproduction of cells to compensate for loss is a recognized pathological principle. Accordingly he assumes that a proper stimulus imparted to a cell will lead to an overproduction to compensate for the loss of substance, while a number of the receptors would be thrown off into the blood and lymph. *These cast off receptors* would then be the antitoxins.

In passive immunity we have to consider some problems involving bacteria that do not to any marked extent produce soluble toxins, samples of which are the bacteria of cholera and typhoid fever. When these microorganisms are destroyed by the serum of an immunized animal it is supposed that their disintegration is due to the co-operation of two substances, an intermediary (or immune body)[1] and a complement,[2] because the normal serum which contains only the complement has no effect on the bacteria.

[1] The complement is an unstable body destroyed at a temperature of about 130° F., and known also as an alexin, defensive substance, ferment, cytase.

[2] Also known as amboceptor, sensitizer, desmon, copula, phytase, etc.

The immune body resists heat, the complement is destroyed by it, but the two must be conjoined so as to produce destruction of the bacteria (bacteriolysis).

Immune bodies may possibly be derived from the cells of immune animals. They vary according to the specific organism. There may be various kinds of immune bodies and complements. Disintegration of bacteria by blood sera also, is largely dependent, it is thought, on the joint action of the complements and intermediary bodies.

In discussing the subject of passive immunity, however, we are brought face to face, not only with a question difficult in itself and very largely theoretical, but complicated by the use of many new terms that are not in general use.

Add to these facts that many of them are synonymous, while the same word may have different significations with different writers, it is clear that the subject has passed beyond the bounds of intelligent discussion, at least so far as many of us are concerned.

It would not be profitable, therefore, to undertake any extended discussion of this subject at the present time, even if the limits of this paper admitted it. It is sufficient to say in conclusion that, according to Ehrlich's theory, if immunity has been *acquired*, his explanation is as follows: The receptors circulating in the blood anchor any of the corresponding toxin molecules before they can reach the cells. And in passive immunity the serum of the immunized individual injected into another individual supplies him with these receptors, and thus confers on him protection against infection.

So far as the clinical side of the attack is concerned, incubation would include both the period when the toxin molecules are grasping the receptors of the cells and also the period during which the toxiphoric agency is acting (the stage of invasion). When the antitoxin formation begins to be established the disease is beginning to yield; where it gains the upper hand, convalescence is at hand.

Now as to the question of *Natural Immunity*. According to Ehrlich either the cells are developing so many receptors that there are always enough in the blood to anchor any toxins or molecules and prevent them attacking the cells, or the cells may have no receptors (processes) fit to grasp the toxin-haptophors. Besides, there must be the right kind of receptors and the right kind of haptophors, and they must be capable of adapting themselves to one another as keys and locks. Thus, for example, the toxins of tetanus tend to affect only the cells of the nervous system.

Ehrlich's theory has of course met opposition, and it will doubtless be modified to meet reasonable objections. But it is convenient for us to accept it provisionally as a good working hypothesis that will be helpful in discovering the principles that govern immunity, whatever they may be.

Latency in Infective Disease.—Latency in dis-

ease has long been recognized. Several explanations are offered. The infecting agent must have been all the time in the system, manufacturing toxins, though not in sufficient amount or quantity to insure symptoms; or the microorganisms may have been in the body in an inert condition, that is, incapable for a time at least of active development.

Now, the latter condition actually prevails in nature. For example, in febrine, a silkworm disease, the pathogenetic microorganism can actually be seen in the eggs. But they do not develop until the growth of the caterpillar begins. In the germ stage of the caterpillar they are quiescent (Lazarus-Barlow).

A relapse, as in typhoid or malaria, is really a fresh access of the disease. How then can we explain these attacks at a time when the patients are presumed to have acquired a certain degree of immunity? So far as typhoid is concerned the explanation may be that the typhoid germs were temporarily locked up.

Thus, in typhoid fever Chiari found of 22 cases taken consecutively, that there were typhoid bacilli in the gall-bladder in 19, and in 13 of these cases the gall-bladder showed hyperemia, edema and infiltration of its walls.

Hence typhoid bacilli must have been locked up, and multiplying have formed these toxins, which could not be discharged owing to the inflammation of the ducts. With the patency of the passages they were discharged into the intestine in such numbers and perhaps endowed with such unusual virulence that they broke down the immunity that was being developed in the cellular tissues.

Now, just such a condition sometimes prevails in the horse when he is being immunized against diphtheria. For an excessive dose either of a toxin or of bacteria, can actually lead to symptoms of the very disease against which the animal was being prepared, notwithstanding he had already attained a fairly high degree of immunity.

In prosecuting the study of these subjects, much has been done, but only by protracted investigations of the most elaborate and painstaking character, while much more remains to be done in the future.

This work, however, can only be done by experts, educated and trained to laboratory methods, and conversant with all the facts and theories that are afloat, and also with the use and misuse of the many self-coined words that investigators have thought necessary to use in expressing their ideas.

And yet it is none the less true, that out of all the present obscurity, facts of great practical importance are being gradually secured.

Already therapeutic principles that have saved countless lives have been established by these researches. But they should be prosecuted with more vigor. In fact, medicine offers the modern philanthropist no larger opportunities, than the prosecution of these subjects by trained men, provided with all the appliances necessary for scientific investigations.

NOTES ON THE EPIDEMIC OF CEREBROSPINAL MENINGITIS.[1][2]

BY HENRY DWIGHT CHAPIN, M.D.,
OF NEW YORK.

EARLY in March of this year, cerebrospinal meningitis, which is endemic in this city, began to increase in the number of those attacked. A glance at the deaths reported from this disease last year in comparison with those reported during the same months of this year shows such a marked increase as to justify us in considering it epidemic. The figures here quoted were kindly furnished by the Health Department.

Deaths from Cerebrospinal Meningitis.—

In the limits of the short paper requested by the President, only a few of the salient points can here be enumerated. It is difficult to briefly draw a clinical picture of a disease so marked by irregularity in its manifestations, but an attempt will be made from a study of cases seen by the author and those reported by colleagues in the various societies. The onset is fairly abrupt, differing markedly in this respect from all other forms of meningitis. In getting a history it is usually possible to date the time of the beginning of symptoms to within a few hours, or even within sharper limits, before which time the patient has been apparently in good health. Generally there is vomiting, chilliness and rigors in older subjects, and frequently severe convulsions. The severity of the initial symptoms is apt to stand in some relation to the type of the attack. Thus prolonged convulsions quickly followed by coma will warrant a grave prognosis. There are exceptions, however, to this rule, as exemplified in a child of 2½ years, recently seen, who had convulsions at the onset lasting, off and on, for four days, and yet she made a good recovery in between two and three weeks. If stupor or coma quickly follow the convulsions, the case will be apt to be severe. In patients old enough to describe symptoms, complaint is made of severe pain in the head and back of the neck. The typical retraction of the head is an early symptom, usually noted on the second or third day. In very mild cases, this may not be so marked, but in average and severe cases, the rigidity is often extreme and hard to overcome. The posture of the patient at this time becomes characteristic, and, with the opisthotonos, the thighs and legs, and even the arms and hands, are apt to be in a condition of more or less extreme flexion. The contraction and rigidity usually continue during the course of the disease. After this characteristic beginning, cerebrospinal meningitis is most

[1] Read before the Medical Society of the County of New York, May 23, 1904.
[2] Received for publication, May 25, 1904.

irregular in its manifestations, particularly in the epidemic type. Cases that appear to be rapidly proceeding to a fatal ending may suddenly improve, and those that do not show very urgent symptoms may just as suddenly and unexpectedly die. A glance at some of the clinical features noted during the course of the disease as here given has been taken largely from cases studied in the children's ward of the Post-Graduate Hospital, with the kind permission of Dr. Caille, who is at present on duty. With reference to the nervous system, convulsions may first be noted. As already stated, the clonic spasms occur early in the disease, but they may be severe and persistent. In one case a baby of three months had repeated convulsions covering a period of five days, and in a case previously mentioned this alarming symptom lasted four days. It is unusual to have convulsions later in the disease. The tonic spasm of the muscular group at the back of the neck is one of the most constant features, with little or no relaxation until late in the disease. Hyperesthesia of the skin is noted, as in all forms of meningitis. The patients show every evidence of discomfort on being disturbed, partly from this cause and partly from aggravation of the pain in the head and neck. The mental state runs the gamut from apathy and indifference to great irritability, delirium, drowsiness, semi-stupor, stupor and coma. Some of the cases went directly from convulsions into stupor and this is very apt to take place. Kernig's sign may be recognized in nearly every case. All of the cases in which the blood was examined exhibited more or less leucocytosis.

The temperature and pulse show remarkable variations and present no characteristic features aside from this variability. There is no apparent cause for these wide fluctuations. One case, a child 3½ years old, is worth special mention. On one occasion the temperature rose to 108.6° F., once to 106.4° F., and three times it was above 105° F. The pulse varied from 100 to 160 and the respiration from 24 to 48. There was initial vomiting, followed by irritability, rigidity of the neck and then marked apathy. An ounce of turbid fluid was withdrawn by lumbar puncture and the *Diplococcus intracellularis* found. Leucocyte count, 21,200. Dr. Davis found neuroretinitis in both eyes. The child is now convalescing favorably. Another case, 6½ years old, had a temperature of 106° F. and 107° F. on the second and third days respectively, after which it gradually dropped to 99° F., the pulse varying from 150 to 85 and the respiration from 44 to 24. An ounce and a half of turbid serum removed by lumbar puncture and *Diplococcus intracellularis* found. Eyes normal. This case has so far done well. Another case, 3½ years old, started with vomiting and convulsions, followed by delirium. During fifteen days the temperature varied between 103.2° F. and 98.6° F., when it rose to 106.4° F. and the child became much worse. As he was apparently dying, the parents wished him removed to his home. Lumbar puncture dry. Mild neuroretinitis of both eyes with dilatation of blood vessels.

While the temperature is thus most irregular and may reach an extraordinary height, some cases may run their course with little increase of temperature. The pulse, while variable, is not apt to exhibit the marked intermissions so frequently seen in other forms of meningitis. The respiration likewise differs from ordinary meningitis in not usually being so irregular and sighing.

In previous epidemics there have been cases of croupous pneumonia reported as occurring during the time that cerebrospinal meningitis was prevalent. The frequency, severity and mortality of pneumonia during the past winter and spring have been noted by all physicians in this locality, thus corroborating previous experience in this respect. The skin seems seldom to be involved in the present epidemic. No case has been seen by the author exhibiting the purpuric spots over the body, from which the old name "spotted fever" was derived. In conversing with others who are seeing cases, the rarity of the eruption has been likewise noted. The eyes are often more or less involved, with dilatation or inequality of the pupils and sluggish response to light. In four cases seen by the author there was a mild neuroretinitis of both eyes and in one case dilatation of the retinal veins on both sides was reported. It is possible for all the structures of the eye to become inflamed, with consequent loss of sight. Some cases exhibit a mild grade of conjunctivitis. The ear is likewise involved in a certain proportion of cases. A subacute inflammation may take the form of an otitis media or an involvement of the labyrinth, followed by deafness.

The general course and duration are most irregular. A mild case may go on to recovery in two weeks, while severer ones last many weeks and even months. The patient may get in a condition of extreme prostration and emaciation and yet gradually go on to recovery. Unfortunately there are cases where the brain is permanently crippled by the ravages of the disease and the patient never regains his former mental and physical strength. The special senses may likewise suffer loss or permanent disability.

The cause of the epidemic form of cerebrospinal meningitis is recognized to be the *Diplococcus intracellularis*, which is found in the fluid procured by lumbar puncture. This fluid is usually turbid when drawn. The diplococcus was found in all the cases thus examined except two, one of the latter giving a dry puncture and the other a clear fluid, the culture from which gave no growth. The manner in which this germ gains access to the cerebrospinal meninges as well as its port of entry appears to be uncertain. The nasal secretions are now being studied, the results of which will doubtless be given in due time by the bacteriologists. In one case, a baby of three months, some turbid serum drawn from the spinal canal showed the diplococcus and an eye-smear was reported to exhibit gonococci or the diplococcus of meningitis. As the eyes were

normal to examination, the latter was evidently the germ recognized. Several mild cases have only been recognized positively as cerebrospinal meningitis by the results of the lumbar puncture. In one case, a young infant, with an obscure history, was admitted to the hospital and, after an examination, there was a question as to diagnosis, as there were no characteristic symptoms present. A lumbar puncture was then performed and the diplococcus found, in the absence of which no positive diagnosis would have been made. Doubtless in this epidemic, as in preceding ones, some mild cases are never correctly diagnosed, especially in young infants. There are no means of knowing how many such cases occur, hence it is very difficult in this as in other epidemics to state the relative mortality of the attacks in different years. We know, however, that the death rate is high. In the epidemic of 1872, 782 deaths were reported during the year in New York, and in 1881, 461 deaths. This included only what now forms the Borough of Manhattan, with a population then much smaller. The disease does not seem to be limited to any one section of the city, but, generally, it occurs in the poorer quarters. It seems to attack by preference those living in unfavorable hygienic surroundings, or those whose systems are exhausted, especially if they live in a depressing environment. While the spread of this disease is certainly a calamity, there does not seem to be occasion for undue alarm in the public mind. The Department of Health is studying the epidemic and doing all in its power under the conditions to find out how the disease extends and acts. It does not behave like a contagious disease that spreads from one adjacent point to another, frequently being traced by transportation, but rather appearing in comparatively isolated localities. Most of the epidemics in this country and Europe have extended principally in winter, so that, reasoning by analogy, the onset of warm weather should have a favorable effect in checking the epidemic's influence.

THE CLINICAL FEATURES OF CEREBROSPINAL MENINGITIS, OR CEREBROSPINAL FEVER OF THE EPIDEMIC TYPE.[1] [2]

BY HENRY KOPLIK, M.D.,
OF NEW YORK.

DURING the past few years additional interest has been given to the study of cerebrospinal meningitis of the epidemic form, due mainly to the investigations, on this side of the Atlantic, of Councilman and his pupils, Osler and others. A severe epidemic of this disease in Boston (somewhat over a hundred cases) has given Councilman an opportunity to study thoroughly the disease from an epidemiological as well as from a pathological standpoint. Osler has been able to study a number of cases occurring in an outbreak in Baltimore.

During the past five years there have been yearly outbreaks of this disease in New York, culminating in an extensive epidemic in the spring of this year. I have thus been able to study quite a number, some 37 cases, of the disease at the bedside, and to analyze carefully its clinical features. In this study I have utilized 77 cases of meningitis occurring in my service in the Mount Sinai Hospital, New York. These 77 cases were divided into the following groups: 37 cases of cerebrospinal meningitis of the epidemic type—21 of which were substantiated by culture and coverglass spread to be due to the *Meningococcus intracellularis*. Of the remaining cases of the epidemic form, some were not substantiated by lumbar puncture being clinically self-evident; others were so-called dry taps; 35 cases were of the tuberculous form of meningitis, as substantiated absolutely either by post mortem or guinea-pig experiment, or by discovery of tubercle bacilli in the lumbar puncture fluids. One case was a so-called staphylococcus meningitis; one case, primary pneumococcus meningitis; one case, streptococcus meningitis. In two cases, so-called pseudo influenza bacilli were found.

In the above statistics I have not utilized 15 cases of cerebrospinal meningitis which belong to the epidemic of the present year. Of these 15 cases, 5 died; of the remaining 10, 5 are still in my ward convalescing. Some of these cases were so classical and self-evident, or the symptoms improved so steadily that they were not subjected to lumbar puncture. The ultimate fate of the remaining cases cannot be stated as yet.

Age.—The ages of the patients affected with epidemic cerebrospinal meningitis confirm the assertion that this affection is a disease of young people. Sixty per cent. of the cases were under two years of age; the youngest was four months of age; 77 per cent. of the cases were under four years of age, the oldest child being fourteen years. The average age was two years. In tuberculous meningitis, however, the average age was somewhat higher, only 41 per cent. of the cases being under four years of age, the average age being four years and four months.

Classification.—In looking over the literature on the subject of meningitis, the most lucid classification is given by Osler. He divides the classification into primary and secondary forms, which will be accepted by all. The primary forms include cerebrospinal fever, both of the sporadic and the epidemic types, and as a separate disease the pneumococcus meningitis. In the secondary forms he includes the tuberculous, the pneumococcus meningitis; the latter being secondary to pneumonia, endocarditis, disease or injury of the cranial bones. Third, there are the pyogenic forms, due to staphylococci, the streptococci, or secondary either to disease of the cranium or local infections. Fourth, are met the forms secondary to typhoid fever, influenza, diphtheria, gonorrhea, anthrax, actinomycosis. Fifth, Osler would include in a separate rubric the so-called serous meningitis, which I may say is to-day being

[1] Read before the Association of American Physicians, Washington, D. C., May 10, 1904.
[2] Received for publication May 18, 1904.

recognized as a secondary form of the disease, due possibly to infection by streptococci or pyogenic organisms. This classification, it will be seen, recognizes both the sporadic and the epidemic forms of cerebrospinal fever as being the same disease and due to the same essential cause.

My own cases are of the primary form of cerebrospinal fever of the epidemic type, including at least one form which may occur sporadically, the so-called posterior basic meningitis of Still.

Bacteriology.—The bacteriological features of my cases were worked out in the laboratory of the Mount Sinai Hospital, under the supervision of the pathological staff. Referring to a report of this work, by E. Libman, published in the Mount Sinai Hospital Reports of this year, it will be seen that all the cases were examined culturally. Reliance was not placed on cover-glass stain alone. All the cultures corresponded to those described by Weichselbaum. None of them, however, showed Gram positive diplococci. There was a variation in the growth on media not containing serum; but when this growth was obtained on such media, it was never profuse.

The conclusion is that there is one type of the *Diplococcus meningitidis* in the New York cases of cerebrospinal meningitis. This type corresponds to that found by Councilman and Wright in Boston; and Osler and Hirsch in Baltimore, and Herrick and others in Chicago. Both the nasal discharges and the conjunctival secretions were studied and in one of my cases the presence of the meningococcus was proven to be present culturally in the conjunctival inflammatory discharge. In this case there was a distinct history of conjunctivitis preceding the attack of meningitis, and the diplococcus was also established in the cerebrospinal fluid. We have never proven the presence of the meningococcus in the secretions and discharges of the nose. We have found, however, the *Micrococcus catarrhalis,* an organism which closely resembles the meningococcus, whose cultural characteristics we will not enter into, but refer the reader to the extensive investigations of this organism by Dr. Celler, my former assistant, and published in the Mount Sinai Hospital Reports of this year.

Clinical Types.—The clinical picture presented by children suffering with cerebrospinal meningitis of the epidemic type is quite characteristic, not only in its onset but in the general course of the disease. I have been able to differentiate certain distinct types in the cases occurring in my hospital service and consulting practice. Previous to the present epidemic in New York, the malignant cases during the past four years have not been as common as they were during the present year. I have recently seen a number of cases presenting the malignant form in which children in previous good health are attacked with the disease, and die within twenty-four or thirty-six hours.

The following case, one of the first of this year's epidemic, is quite a characteristic example of this type of the disease: An infant twelve months old, nursed at the breast, perfectly formed, a large, healthy, bright child, never previously affected by any illness; nursing and bowels normal. On the morning previous to the day on which I saw the case with the family physician, the child appeared sleepy, stupid and refused the breast. It vomited, but was not feverish. That evening the physician was called in and found the infant quite drowsy and listless, with a temperature of 103° F., pulse 110 and very weak. There was no peculiarity about the eyes, no stiffness of the muscles of the neck or body. At 3 and 5 A.M., on the following day the child awoke crying and the mother discovered some red spots on the cheeks. The face was slightly swollen, the eyes staring, and the child was apparently blind. By 8 A.M., the entire face, hands and body were covered with blotches which turned bluish; the tissues of the extremities seemed to be hard and swollen; the buttocks and body looked as if the child had been beaten, ecchymosis being quite extended over the body and extremities when I saw the child. At this time the temperature was 101° F. and the pulse very weak, scarcely to be felt at the wrist; the lips were blue; the reflexes abolished. When I saw the child she had no rigidity of the muscles of the neck; there was no Kernig symptom; the pupils were uneven and did not react; there was a slight conjunctivitis; an examination of the lungs, abdomen and ears gave a negative result. The breathing was irregular and catchy, the pulse very rapid and scarcely to be felt at the wrist. The diagnosis of cerebrospinal meningitis was confirmed by a lumbar puncture, made post mortem, a cloudy fluid, milky in color, being drawn off, and the intracellular diplococcus of Weichselbaum being found in the fluid, both by stain and culture.

Since seeing this case, I have seen at least three others, each presenting similar features. In two of these rapidly fatal malignant cases the hemorrhages thus mentioned were preceded by an erythematous rash.

Another type of cerebrospinal meningitis is more commonly met with in which a child in apparent health is suddenly taken with dizziness or vertigo, vomiting follows, accompanied by severe headache, and then the child passes through the different phases of the disease which are well known and described in books on the subject.

A more puzzling type of cerebrospinal meningitis in infants and young children is that in which a child in apparent health is suddenly found to have a temperature, is restless, refuses the breast, vomits once or twice, and then for weeks will run an intermittent type of temperature, as high as 104° or 105° F., falling to the normal or subnormal daily. In the intervals of freedom from temperature the children or infants will play, and then when the temperature rises they may complain of slight headache, become drowsy, irritable and refuse nourishment. In these cases the typical signs of meningitis are not always present. The delirium may not be constant or may not

extend over the twenty-four hours. The rigidity at the back of the neck may not be very marked, especially in young infants. In these cases also, the children may not have a marked Kernig symptom, especially if below two years of age. The most characteristic feature about these cases it seems, is the prolonged period of temperature of an intermittent type closely resembling malaria. In fact, the attending physician in many of these cases has examined the blood for the malarial plasmodium; or attention has been drawn by the intermittent type of the temperature to the ears in the hope that some focus of suppuration would be found. In other words, these infants and children may continue over a period of weeks with this peculiar temperature, and the onset of the disease has not been marked by convulsions or any of the classical symptoms of meningitis; and still a lumbar puncture in these cases will reveal the presence of the intracellular meningococcus in the fluid thus obtained.

In young infants, the type of the disease most commonly met with is that in which the onset is sudden, marked with general convulsions, high fever, vomiting at the outset, the high fever of the intermittent or remittent type, continuing over weeks. After the fever has lasted for some days or weeks, the mother will notice the rigidity of the head, the irritability of the child and the marked emaciation.

The Mode of Onset.—In all the cases that I have had an opportunity to study in hospital service, in which the diagnosis was confirmed, the main characteristic of the onset of the disease was that it was abrupt. Observation has shown that children in apparent health would suddenly be attacked by the symptoms just detailed. In only a small percentage of cases has there been a doubtful history of the sudden onset. In this respect, the disease differs markedly from the meningitis of the tuberculous type, which is of slow onset, and in only a small percentage of cases is such a history doubtful.

Neck Rigidity.—Great stress has been laid by some authors on the presence or absence of neck rigidity. As has been hinted, there are some cases in which rigidity is not present at all times; but if these cases are observed for any length of time, our experience shows that slight or marked rigidity is present at one time or another in all cases of cerebrospinal meningitis. Opisthotonos is present in about 70 per cent. of the cases. In the posterior basic forms, of which we will speak later, the rigidity and opisthotonos is so marked that the child will assume the position seen in tetanus, being perfectly rigid, curved backward, the forearms extended, the fingers clenched in the palms; these are cases which only form a small percentage of the total number seen in an epidemic, and they affect mostly younger infants and children. According to Osler, neck rigidity or opisthotonos was not present in the adult form of primary pneumococcus meningitis. Rigidity was present in my own case of primary pneumococcus meningitis confirmed by autopsy. In our case, not only was rigidity present but also opisthotonos.

Reflexes.—In a majority of cases of epidemic cerebrospinal meningitis, the skin, tendon, and plantar reflexes were present in the early stages of the disease, but were apt to disappear in the rapidly fatal cass, or in moribund cases.

The Babinski Reflex.—Babinski, a French neurologist, described the extension of the great toe on irritation of the plantar surface of the foot as a characteristic sign of disease of the pyramidal tracts or the lateral columns of the cord, and we have studied this sign in the forms of meningitis coming under our notice. We have found that in meningitis of the epidemic cerebrospinal type, it was present in 4 of 25 cases studied. This is in marked contrast to what is found in tuberculous meningitis, in which this reflex was absent in only 6 cases of the 26 in which it was sought. In other words, it was present in 77 per cent. of the cases of the tuberculous form of meningitis, and I regard the presence of this reflex as a valuable addition to the clinical picture of tuberculous meningitis as distinguished from cerebrospinal meningitis of the epidemic type. I can only explain its constancy in tuberculous meningitis by the fact that in these cases there is possibly an invasion, either directly or indirectly, of the pyramidal tracts or the lateral columns of the cord by the disease. The sign is of very little value, however, in children and infants below two years of age, for it may at times be seen in perfectly normal infants, or in those suffering from various affections. This seems also to be the conclusion reached by Morse, of Boston, who contends that the Babinski sign is quite inconstant in its manifestations in infants and children below two years of age.

The Kernig Symptom.—Much has been written about this very interesting symptom, the contraction of the flexor muscles of the lower extremities, as seen in cases of meningitis. I have found that the Kernig symptom is of very little utility in infants and children below two years of age. Of course, in infants, especially under one year, there is a normal tendency toward myotonia. Even superficial observation will show that normal infants are apt to lie with their lower extremities flexed, assuming very much the position of the fetus in utero. In children below two years of age suffering from meningitis, the irritability is so great that it is impossible to come to any conclusion as to the presence or absence of the Kernig symptom. In all the cases of cerebrospinal meningitis of the epidemic type above two years of age, therefore, the Kernig symptom was present. In cases of tuberculous meningitis, its presence was not so constant, being absent in eight cases of 26 in which it was sought. I do not lay too great stress upon the presence of the Kernig as a pathognomonic sign of meningitis. It may be present in cases of which we are accustomed to say that there are cerebral symptoms without meningitis as in typhoid fever or pneumonia.

Hyperesthesia and Mental Irritability.—In the

majority of cases of epidemic cerebrospinal meningitis, after the usual symptoms have set in and the disease is well inaugurated, the children, and even infants, are irritable, refuse to be comforted, start at the least sound in the room, lie mostly on the side, the arms and lower extremities flexed, the body taking the crouching position. Any attempt to disturb the patients is met with resistance. In the present epidemic, although many cases have been exceedingly mild, hyperesthesia of the surface, and irritability of the mind was very marked in all cases. In past epidemics of 21 cases hyperesthesia of the surface was quite marked in fully 62 per cent. of the cases.

In marked contrast to the above is the absence in the tuberculous form of the disease of any reaction or hyperesthesia of the surface. The child lies in a stuporous condition, does not notice its surroundings; whereas in the epidemic cerebrospinal meningitis, when not comatose, the children are alive to their surroundings, or are irritated by some things passing on around them. In the tuberculous forms of meningitis, hyperesthesia was present in only three of 34 cases. In other words, it was absent in 90 per cent. of the cases.

The MacEwen Sign.—MacEwen has pointed out that in children in various forms of meningitis we obtain on percussion a hollow note over the anterior horn of the ventricle. If the head is so held that the anterior frontal or parietal bone may be percussed over the situation of the anterior horn of the ventricle, this note will be produced. That is, if the patient sits upright and the head is inclined to one side, percussion of the inferior frontal or parietal bone will give a tympanitic note.

I have found that in 17 cases of tuberculous meningitis in which this note was sought, that it was present in 11, and it has seemed to me to be exceedingly valuable in making up the clinical picture of the tuberculous forms of meningitis. MacEwen thinks that the note is caused by the presence of fluid, so-called hydrocephalus, in the ventricle. In meningitis of the epidemic cerebrospinal type, however, this note is not obtained in the majority of cases. In 13 studied with this object in view, it was present in only two, showing the difference in this respect between the two forms of meningitis. In other words, if MacEwen is correct, there is very little distention of the ventricle with fluid in the first stages of the disease. In the chronic cases, however, with an increase of fluid in the ventricles and these are the cases in which the note was obtained I have found quite a marked MacEwen present.

Facial Paresis.—As is well known, facial paresis is quite a constant feature of the tuberculous forms of meningitis, and in 35 absolutely substantiated cases of tuberculous meningitis, it was found in 19 early in the disease; and it appeared toward the close in most of the cases. In epidemic cerebrospinal meningitis, however, facial paralysis occurs only in the severest types of the disease where the intracranial pressure to one side or the other, especially at the base, is quite great, and in 21 cases in which it was looked for, facial paralysis, marked or slight, was present in only three cases.

Temperature.—One of the prevailing types of fever in children in the cases we have observed was that of the intermittent type, in which the temperature would be quite high at some time of the day, and normal or subnormal at another. The range of temperature would sometimes be very marked, four, five, six or eight degrees. In one case which I have under observation of the basic form of Still, the temperature reached fully 106° to 106.5° F., falling to normal or subnormal at some time during the day. The temperature curve in epidemic cerebrospinal meningitis cannot be said to be characteristic, and at times will exhibit the wildest irregularities.

The Skin.—In most of my cases I have not been able to find the prevalence of the rashes described by most authors. This is due, possibly, to the fact that in the epidemics I have observed, skin rashes and eruptions were not common. On the other hand, herpes, referring especially to herpes of the lip, is also not very common, and was present in only two of 20 cases. In the adult, however, Osler has found petechiæ, erythematous rash, or herpes, in 13 of his 21 cases. In the epidemic of this spring I have observed a number of cases in which a roseola, closely resembling that seen in typhoid fever, was present. Lately I have seen a number of cases with a profuse petechial rash at the outset of the disease.

Eyes.—Contrary to what is the generally accepted opinion, we have found that expert examination of the fundus revealed no changes in the optic papilla in the majority of our cases of cerebrospinal meningitis, although in some there was dilatation of the veins, or congestion without neuritis. In only one case was there descending neuritis. In a group of 26 cases of meningitis of the tuberculous variety, examined by our expert, Dr. Gruening, some change was found in fully 77 per cent. of the cases. This change consisted either of an optic neuritis or papillitis, or the presence of tubercles in the choroid. In this group of 20 substantiated cases of tuberculous meningitis, 7 showed tubercles in the choroid. It would seem, therefore, that the condition of the fundus, aside from the positive discovery of choroid tubercle, gave us important presumptive evidence of the nature of the meningitis.

The Blood.—Every case of meningitis coming under our observation, including those of the cerebrospinal epidemic type, has been examined with reference to the leucocytosis present. The leucocyte count in all of our cases was made at intervals of three days in the course of the disease. In all of the cases of epidemic cerebrospinal meningitis there was leucocytosis to some extent. The leucocytosis was of the polynuclear type, the leucocytes ranging from 20,000 to 55,000, exceeding 25,000 to the cubic millimeter in fully 55 per cent. of the cases. The lowest leucocyte count in any case was 11,100 to 12,000 to the cubic millimeter.

This corresponds very closely to what was found by Osler to be true of the adult cases. In the tuberculous forms of meningitis in infants and children, we have not always found a so-called leucopenia. On the contrary, in fully 40 per cent. of the cases there was a leucocyte count of 20,000 to 25,000 to the cubic millimeter; and under 20,000 in 60 per cent. of the cases. In no case, however, did the leucocyte count exceed 24,000, except in one case of tuberculous meningitis, in which we obtained a leucocyte count of 32,000. The leucocyte count which has just been mentioned (with the exception of the one last referred to) having been made in 26 substantiated cases of the disease, would seem to be an important feature, if we compare it to what is true of the adult. In Osler's cases of tuberculous meningitis, leucocytosis was absent in only three cases; his highest count (24,333) corresponds so closely to what we have found true of our own cases in infants and children, that we are apt to be led to the conclusion that a higher leucocyte count in tuberculous meningitis is exceptional, and, if higher, would speak more for a meningitis other than tuberculous in any given case.

I have studied the leucocyte counts on both the cured and fatal cases with a view to determining whether any conclusion as to prognosis could be drawn from the results of a leucocyte count. In six cases, which recovered, we had the following results:

Case I.—Six years of age; observed from the fourth to the eighteenth day of the disease; leucocytes, 16,800 to 24,000. Puncture fluid clear.

Case II.—Twenty months of age; observed from the fifth to the fortieth day; leucocytes 15,000 to 45,000, the latter toward the twenty-first day of the disease. Puncture fluid clear.

Case III.—Four and one-half years of age; observed from the fifteenth to the eighty-fifth day of the disease; leucocytes, 15,000 at the outset, 34,000 at the midperiod, 21,000 in the convalescence. Puncture fluid turbid.

Case IV.—Five months of age; leucocytes 20,000 to 22,000. Puncture fluid clear.

Case V.—One year of age; observed from the fifth to the fiftieth day; leucocytes, 14,000 to 28,000, the latter in the midperiod of the disease; 15,000 toward convalescence. Puncture fluid clear.

Case VI.—Two years of age, admitted on the fourth day of the disease with a leucocyte count of 40,000. Puncture fluid clear.

Taking a like number of fatal cases, we had the following counts:

Case I.—Four months of age; observed from the twelfth to thirty-seventh day of the disease; leucocyte count from 17,600 to 23,200, the low count at the close of the disease. Puncture fluid thick and turbid.

Case II.—Four months of age; observed from the twelfth to the twenty-ninth day of the disease; leucocyte count from 32,600 to 34,000. Puncture fluid cloudy.

Case III.—Six years of age; observed from the fifth to the fourteenth day of the disease; leucocyte count early of 30,000. Puncture fluid purulent.

Case IV.—Three years of age; observed from the ninth to the eighteenth day; leucocyte count ranging from 34,000 to 55,000. Puncture fluid cloudy.

Case V.—Ten months of age; observed over six weeks; leucocyte count from 10,600 to 26,000, the latter toward the close. Puncture fluid turbid.

Case VI.—Six months of age; observed from the twelfth to the forty-seventh day of the disease; leucocytes, 28,000 to 17,600 early in the disease, and 9,800 to 18,200 later on, the lower count at the close of the disease.

It may be stated that in the so-called basic cases in infants and young children the leucocyte count early in the disease may range from 32,000 to 34,000, but toward the close when the temperature rarely rises above the normal the leucocyte count may fall as low as 9,800 to 10,600. In this respect the leucocyte count resembles what is found in cases of tuberculous meningitis; and these cases on account of this have been mistaken by some for tuberculous meningitis. The leucocyte count in the fatal cases in which the fluid obtained by lumbar puncture is quite turbid, with a sediment resembling pus, is apt to be high, mounting to 35,000 to 55,000. On the other hand, fatal cases with a thick turbid fluid on puncture, may give a count not exceeding 23,200.

Cases which have recovered, showed a leucocyte count of 14,000 to 28,000 during the course of the disease; the leucocytes may have mounted as high as 45,000, as in one case on the twenty-first day of the disease.

It cannot, therefore, be said that a prognosis as to the recovery or fatal issue can be made from the leucocyte count alone without taking into account the duration of the disease and the character of the lesion as revealed by clinical methods of precision.

Characteristics of the Cerebrospinal Fluid Obtained by Lumbar Puncture.—So much has been said of the physical characteristics of the fluid obtained by lumbar puncture in cases of meningitis, either of the epidemic cerebrospinal, the tuberculous, or the suppurative forms, that the writer scarcely deems it proper to repeat what has been said upon this subject. The cytology of the fluids obtained by lumbar puncture in cases of cerebrospinal meningitis is of particular interest as regards the possibility of making a diagnosis from the elements found in the fluid alone, apart from the bacteriology. Of 13 cases studied with reference to the cytology, nine showed a preponderance of polynuclear leucocytes; and four showed mononuclear cells as prevailing elements. It would seem, therefore, that in the majority of cases of cerebrospinal meningitis of the epidemic type, the lumbar fluid presented a polynuclear leucocytic picture. In 15 cases of tuberculous meningitis, studied with a view to noting the character of the cell elements, 14 showed a prevalence of the mononuclear cells, and one case an equal

number of mononuclear and polynuclear cells. In the above studies all the fluids were subjected to careful centrifuge.

It would seem, therefore, that in tuberculous meningitis there is a prevalence of mononuclear cells, and this is so constant that it would seem to us to be characteristic, and verifies what is known from publications on this subject. It will be seen, however, that there are cases of cerebrospinal meningitis of the epidemic type, three of which we have noted, in which there is a cytological picture closely resembling that seen in tuberculous cases. In chronic cases, instead of a predominance of polynuclear cells in the sediment of the fluid obtained by lumbar puncture, the mononuclear picture is apt to present itself, closely resembling what is seen in the tuberculous cases. This is especially true of the chronic cases of cerebrospinal meningitis of the basic type described by Still. Bendix explains this variation from what might be called the normal picture in cerebrospinal meningitis by the fact, proven by Ribbert, that in chronic inflammations lymphocytes abound in the transudates; whereas in acute inflammations, leucocytes abound.

It seems to us that the physical characteristics of the fluid obtained by lumbar puncture aid us but little in coming to a conclusion as to the form of meningitis present. In cerebrospinal meningitis of the epidemic type we have obtained fluid which has been quite clear, with scarcely any sediment, cloudy varying to the purulent fluid; whereas in the tuberculous forms of meningitis, the fluid was clear in 72 per cent. of our cases, but was quite cloudy in others, and more or less cloudy in the remaining number of cases. In all the epidemic cerebrospinal cases which we consider as substantiated either by the clinical picture or the results of lumbar puncture, the *Diplococcus meningitidis* was found at one time or another in the puncture fluid. In one case it was found in two successive punctures, and in a third puncture it was absent and failed to give any culture when spread on media; and in a fourth puncture the diplococcus reappeared. To my mind this simply means that in the fluid obtained in the third puncture, the diplococci were so few in numbers as to elude search conducted with the ordinary care.

The earliest period at which we have found the diplococcus in cases of cerebrospinal meningitis of the epidemic type, was within twenty-four hours after the onset of the disease; and we have established it as late as the fifteenth week of the disease. It is apt to elude search and fail to give any result on media in chronic cases, especially of the posterior basic type.

In this connection, the bacteriology of the fluids obtained from cases of tuberculous meningitis is of interest, and it may be said here that there has been much difference of opinion as to the presence of tubercle bacilli in fluid obtained by lumbar puncture in cases of tuberculous meningitis. Whereas, Lichtheim, Lenhartz and Bernheim found that tubercle bacilli were constant in the sediment of the fluid obtained from tuberculous meningitis; others, such as Cassell and Marfan have asserted that their presence is only occasional. Our experience in this regard supports the contention of Pfaundler, that the discovery of tubercle bacilli in the fluid obtained by lumbar puncture in tuberculous cases depends much on patience and technic. This is well seen in our own cases. At a time when our technic was imperfect, when we did not centrifuge our fluids carefully, we failed to find the tubercle bacilli. Of late, however, we have made a special study of this question, and during the past year, of 14 cases diagnosed by me clinically as tuberculous meningitis, tubercle bacilli were found in 13 by subsequent lumbar puncture by Dr. E. P. Bernstein, of the pathological staff. To my mind this would prove absolutely that tubercle bacilli can be found by careful search in the puncture fluid of all cases of tuberculous meningitis. In some cases the search must be quite prolonged. In other cases, especially of children brought in late in the disease, we failed to obtain tubercle bacilli in the puncture fluid before death; but they were found to exist in abundant numbers in the fluid obtained by puncture immediately after death. It is hard to account for this apparent inconsistency, but I explain it by the fact that there is during life probably a constant wave of motion in the cerebrospinal fluid, thus securing the equal distribution of the bacilli throughout the cerebrospinal space. As soon as death occurs, this circulatory wave is suspended and a sedimentation occurs and the bacilli are thus obtained in the lower part of the canal.

Mortality.—It need not be said here that in epidemics of cerebrospinal meningitis the mortality among children will vary largely not only with the severity of the epidemic, but with the malignancy of the infection. In some epidemics the malignant cases, that is those which die within twenty-four or forty-eight hours, seem to be more numerous than in other epidemics. Of 37 cases in five years' service previous to the present year which clinically presented all the classical features of cerebrospinal meningitis, 21 were absolutely substantiated either by lumbar puncture or post mortem to be of the epidemic type. Of these 21 cases, the mortality was 42.8 per cent. Of the whole number of 37 cases, the mortality was 35.6 per cent., some were not punctured because the symptoms were self-evident, others were punctured but failed to yield but little fluid, with negative bacteriological results. Most of the fatal cases occurred in infants below one year. Of 15 fatal cases, eight were less than one year of age and two below two years. Thus, the older the child the better its chances of conquering the infection. I have records, however, of cured cases in infants of five months, and one one year of age, in which the diagnosis of cerebrospinal meningitis of the epidemic type was substantiated by cultures from the fluid obtained by lumbar puncture.

Complications.—In the 37 cases of epidemic cerebrospinal meningitis which form the basis of

this paper, we have noticed that the complications were exceedingly few. Those cases that recovered did so with very little to show that the nervous system in any of its extent had been severely compromised. The eyesight was not injured, nor was there in any of the cases, a subsequent hydrocephalus. In other words, the recoveries when they occurred were complete and satisfactory. This is, of course, not due to any modes of treatment employed but to the nature of the cases.

The most common complication seemed to be otitis. Herpes labialis was found in only two cases of the 37 and none of the cases presented joint complications, in this respect differing from the joint complications in the adult. I have lately seen one case of joint involvement. Erythemata and evanescent eruptions were observed here and there.

Most peculiar and striking have been several cases of the malignant type which I have seen this year in which death took place within twenty-four hours after the initial symptoms appeared. In both of these cases there was a scarlatinous erythema. This disappeared and was replaced by a purpuric eruption, extensive in character, the skin of the infants and children appearing as if they had been beaten. Ecchymoses were blotchy and of wide extent distributed over the back, thorax, abdomen and upper and lower extremities. The diagnosis in these cases left no question of a doubt, being substantiated by the presence of meningococcus in the fluid obtained by lumbar puncture.

Posterior Basic Meningitis.—Still, of London, has given peculiar interest to this form of meningitis through his investigations of 15 cases of the disease. His clinical summary of the characteristics of these cases is quite classical and may be mentioned here for the sake of completeness: An infant becomes fretful, irritable, peevish, has one or more convulsions, vomits, and then in a few days the mother notices that the head is drawn backward, the limbs are rigid, and there is partial or complete opisthotonos. Quite a percentage of these cases last for weeks and may recover; others pass into the chronic stage, which may last for months, with complicating hydrocephalus. During the course of the disease, the rigidity of the neck, the retraction of the head, becomes extreme, and finally the infant passes into a condition resembling a tetanic state, with its arched back, its retracted occiput, the upper extremities in the position of extension, the hands clenched, very much as is seen in forms of tetany. The lower extremities remain in a condition of rigidity and of extension, and the feet and toes both extended. It was formerly thought that these cases were tuberculous; but Still has found that in 13 of his 15 cases he could isolate a diplococcus which to-day may be considered identical with the *Diplococcus meningitidis.* Still and Nuttall both consider this form of meningitis a type of sporadic spinal meningitis, with the same etiology as that of the epidemic cases. Any one who has much to do with infants and children has seen these cases, and I have seen quite a number of them.

These cases have come to me in the hospital in the subacute stage, and, as is very often the case, I have had no opportunity until recently to make a post mortem in a case of basic meningitis. In one case the fluid withdrawn by lumbar puncture was quite clear, resembling that of hydrocephalus. The fontanelle was bulging to a considerable extent, being open, and we drew off considerable fluid by repeated lumbar puncture. We have been unable, however, to cultivate the *Diplococcus meningitidis* from this fluid. The cytology in this case to which I refer showed a preponderance of mononuclear lymphocytes. In none of the cases have we been able to prove the tuberculous nature of the disease by the injection of cerebrospinal fluid into animals, and this I am inclined to believe would support the contention of Still that this type of cases is distinctly caused by the *Diplococcus meningitidis* and is to be classed with the epidemic cases.

I have recently been fortunate in obtaining a post mortem on a case of posterior basic meningitis in the puncture fluid of which I obtained the *Diplococcus intracellularis* both by cover glass stain and culture. The history of the case is as follows:

Female child, aged two years, with a negative family history. The child had been born normally, had not suffered from any infectious disease; although a year previous had an abscess in the neck, which was cured in three weeks. No history of ear trouble; has always been a healthy, bright child.

Present History.—The illness was of five weeks' duration, began suddenly with fever and general convulsions; since then the child has felt better at times, and at other times, chiefly toward evening, the symptoms have reappeared. The child became stuporous since yesterday. The father thinks it is blind; it has vomited occasionally for the past three days. There have been sudden movements of the upper and lower extremities. During this illness the child has become much emaciated. There is no cough. The bowels and urination are normal. No previous history of traumatism. The father has not noticed any enlargement of the child's head during the illness.

Present Status.—The child lies with its head retracted and body slightly curved, the concavity somewhat to the left. There are occasional purposeless movements of all the four extremities, more marked on the right side. These are sometimes so limited as really to constitute tremors. The child starts at the least sound. Is unconscious. The eyes are open, pupils dilated, though they react to light. The forearms are extended from the arms, the hands clenched; the lower extremities are extended, the feet extended, as also the toes are flexed into the plantar surface of the foot. At times the child is rigid. There is rigidity at the back of the neck, and this rigidity is increased if the child is handled. At such times,

there is extreme opisthotonos, the head is drawn back at an angle to the trunk. In other words, there is a spastic condition of all the extremities. The knee-jerks are increased; there is no clonus. The spasm at times is extreme, and a good deal of force is necessary to move the hands or legs. There is a tâche cérébrale. The respirations are very irregular, sometimes superficial and at others deep. There is no paralysis either of the muscles of the face or those of the orbit of the eyes. The ears are negative; heart and lungs show nothing peculiar. The liver normal to percussion; spleen palpable just below the free border of the ribs. Abdomen retracted. The skin shows a slight erythematous rash on the trunk. The throat cannot be examined on account of the fixity of the lower jaw (trismus).

The further history of the case is uneventful. The temperature was normal on admission, rose toward the close to 101° F. The pulse ranged from 100 to 140, being quite irregular at times. The respirations ranged from 28 to 48. Toward the close, the opisthotonos retraction of the head and rigidity became very marked. The child presented all the features that are characteristic of basic meningitis. The lumbar puncture was made in this case two days before the fatal issue, the child dying four days after admission to the hospital. A flocculent fluid was obtained which showed the presence of 73 per cent. polynuclear leucocytes, and 27 per cent. mononuclear lymphocytes. The spreads and culture of the puncture fluid showed the *Diplococcus intracellularis*, negative to Gram. There was no sugar in the fluid. The child died suddenly in the afternoon of the fifth day after admission. A post mortem was obtained on the brain alone, and showed a classical basic meningitis, as described by Still. The convexity showed only slight meningitis; congestion was marked and there were areas of opaque tissue in the pia or old organized foci of inflammation.

In the post mortems made by Still, he found as an accidental complication recent or old tubercles in a few cases; but in these very cases he has been unable to find any tubercles of the brain or cord. On the contrary, he has established a diplococcus in the ventricular fluid, and therefore considers the tubercles as an accidental complication and not a primary cause of the disease.

Treatment.—The more we study the methods of treatment pursued in the management of cerebrospinal meningitis, the more we are led to the conclusion that the disease, very much like pneumonia, is a self-limited one, and that all we can do is to relieve the suffering of the patient and treat the complications. The results of treatment seem to be very closely connected with the severity of the epidemic, and that of the infection in the various epidemics. Thus, in an epidemic in Oporto there is a record of 56 deaths in 91 cases, a mortality of 62 per cent. In other epidemics, the mortality has been quite low, 25 per cent., and in others higher than this percentage, as may be seen by referring to the section on mortality. And still in these epidemics very much the same treatment has been pursued, if we except one procedure, viz., that of lumbar puncture.

Much has been expected of lumbar puncture, and still, it must be said, comparatively little has been realized from it, in a therapeutic sense. Seager, in recording the mortality and treatment observed by him in cases of epidemic cerebrospinal meningitis, shows that by simple lumbar puncture 9 cases in 20 died, a mortality of 45 per cent. In the treatment by baths, 60 per cent. died. He then gives the statistics of the latest procedure, that of lumbar puncture, followed by the injection of a number of c.c. of a one-per-cent. solution of lysol. Of 31 cases treated by such an injection into the cerebrospinal space, 13 died, a mortality of 42 per cent. In the same clinic where Seager observed these procedures, seven cases were treated with an injection of oxycyanide of mercury, and four died. Neither of these procedures prevented relapses in the cases observed by Seager, and these were quite frequent. In the epidemic in Oporto, 26 cases were treated by simple lumbar puncture. Of these, eight died, a mortality of 30 per cent.

In considering the benefits of lumbar puncture in an epidemic of cerebrospinal meningitis, there are some, such as Osler, Wentworth, Concetti, Travers Smith and others, who think that this procedure is of decided benefit to the patient, inasmuch as headache and delirium are often relieved.

My own experience, and this is considerable, teaches me that we cannot say as yet that lumbar puncture is curative. Indeed, it cannot prevent relapses, as I have proven to my own satisfaction in cases in which the temperature had dropped after lumbar puncture, remained normal for a week, and then, without any apparent cause, a new attack was inaugurated. The fluid after the last puncture having been quite clear and sterile, possibly on account of the paucity of microorganisms, became very turbid again and there recurred an intermittent curve, lasting over three weeks. I have seen the temperature rise after lumbar puncture, and the patient on the surface did not seem to have been benefited; but on a close study of the cases, I have found that the temperature is not a guide as to the efficacy of the procedure of lumbar puncture. Lumbar puncture certainly relieves symptoms of pressure, for in older children who can describe their sensations, there is much relief after the withdrawal of 40 or 50 c.c. of fluid from the cerebrospinal canal. In fact, in one case, I remember distinctly a little patient of twelve years who actually requested (so severe was the headache) that the procedure should be repeated, inasmuch as it was the only thing that gave her relief. Therefore, if the irritability is great and headache is severe, as may be judged even in children by the rational symptoms, lumbar puncture is indicated.

Again, if rigors are frequent, lumbar puncture is certainly indicated inasmuch as a certain amount of purulent exudate is thus withdrawn

in the same sense as it would be indicated in a pleurisy.

Lumbar puncture is inefficient in certain types of cases in which there is extreme retraction of the occiput, rigidity and even opisthotonos (basic meningitis). In some of these cases, introduction of a needle it attended by no results; that is, there is a dry tap. It has been shown that in these cases there is danger of sudden dilatation of the ventricle, and what might have been relieved by the only procedure known in medicine, lumbar puncture, fails in the very cases in which it is most needed.

Again, lumbar puncture gives us a very good idea, in a prognostic sense of the future fate of some cases. Where the cerebrospinal fluid is thick and purulent, and flows slowly from the canula, the prognosis is grave. I have not succeeded in saving any of these cases. Particularly encouraging are the cases in which the fluid obtained by lumbar puncture is of a cloudy appearance, at most showing a straw color.

In a procedure in which so little is known as to its efficacy, it is quite to be expected that all sorts of modifications should have been suggested. I refer to the injection of chemicals or antiseptic fluid, such as lysol and the oxycyanide of mercury. To my mind, none of these procedures has lessened the mortality.

Our treatment has consisted simply of a lumbar puncture whenever indicated by high temperature, continued excessive irritability of the patient, stupor, constant headache, and delirium or rigors. Following out this method, we have felt that we had at our disposal a very excellent method, not only of relieving these symptoms, but of relieving pressure on the vital organs, the brain and cord, at the same time withdrawing from the cerebrospinal space a certain amount of purulent fluid. In view of the fact that the bacterial life of the meningococcus seems to be a self-limited one, I doubt very much whether the procedure of lumbar puncture has a direct influence in shortening the disease. In younger infants and children, however, I do think that repeated lumbar puncture might aid materially in preventing certain complications, such as hydrocephalus following cerebrospinal meningitis, which, as you all know, is a very serious consequence with which to be confronted. Therefore by relieving the pressure, we may possibly prevent in these young subjects a tendency which is present to dilatation of the ventricles and the accumulation of fluid therein.

Our experience with lumbar puncture has been quite extensive. We have never had an accident which could be attributed directly or indirectly to the procedure. Our method of performing lumbar puncture has followed closely that advised by Quincke. If we were unsuccessful and obtained what is known as a dry tap, we have repeated the puncture in another space, but we have not gone further than this. In several cases the primary puncture was followed by quite a profuse hemorrhage. Quincke thinks that this hemorrhage can be traced to the puncture veins in the subdural space. In none of the cases in which hemorrhage occurred have we seen any ill effects follow. In fact, the cases in which hemorrhage occurred made a good recovery without paralysis, especially of the lower extremities.

A peculiar symptom, which I have not noted elsewhere, is that of a desire to urinate at the time of the entry of the trocar in the cerebrospinal space. This, however, is only momentary, and disappears as soon as the trocar is withdrawn.

As to the number of times which a case should be punctured, there is, of course, no set rule. If the temperature remains down after a puncture, and the irritability and headache are not very marked, it is well to hold our hand. If, however, there is a subsequent rise of temperature we may puncture, though certainly not more often than at intervals of four or five days.

As to the quantity of fluid withdrawn in every case, this will vary. In some cases the fluid flows very rapidly from the canula; is quite clear, or slightly turbid, and in a very short space of time 70 or 80 c.c. are withdrawn before there seems to be a relief of tension, which is judged principally by the rapidity with which the fluid flows from the canula. If the fluid flows slowly, drop by drop, we rarely withdraw more than 30 c.c. at a sitting.

Our further treatment, as published elsewhere, has consisted of hot baths for the rigors; sponging, for the temperature; the intestinal canal was kept open with calomel, and we have administered in all of our cases iodide of potassium and sodium in full doses.

I have never made a so-called cervical puncture; nor do I think that lumbar puncture can be ranked with aspiration of the chest as an emergency procedure. Thus, given a case of cerebrospinal meningitis with a very high pulse, such as has occurred in my practice lately of 200, a condition of coma, and all the symptoms of malignant cerebrospinal meningitis, lumbar puncture has seemed of little avail, as practised to-day.

In conclusion I wish to express my thanks and appreciation to my former assistant at the hospital, Dr. C. F. Jellinghaus, who carefully compiled the statistics of this work.

A PLEA FOR THE ORGANIZATION OF A "SOCIETY OF SANITARY AND MORAL PROPHYLAXIS."

BY PRINCE A. MORROW, M.D.,

OF NEW YORK;

EMERITUS PROFESSOR OF GENITO-URINARY DISEASES IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

IT is proposed to form in this country a *Society of Sanitary and Moral Prophylaxis,* the object of which is the study of the means of every order —sanitary, moral and legislative—(the legalization of prostitution excepted) which promise to be most effective in preventing or diminishing the spread of diseases which have their origin in the Social evil. This Society is to be composed of medical men, representatives of the clergy, of the law—public educators, sociologists and public-

spirited men generally—similar to societies which have been organized in various cities and countries of Europe.

At first glance it might appear that the prophylaxis of these diseases, as of other infectious diseases, dangerous to the public health, lies exclusively within the province of the medical profession. But experience has shown that this class of diseases cannot be dealt with as a purely sanitary problem, they are not susceptible to the application of the sanitary methods ordinarily employed against contagious diseases. Sanitary science must take cognizance of the cause of disease and especially of the means by which it is spread. The cause of these diseases resides in social conditions which the sanitarian cannot control and their communicative mode cannot be reached by the strong arm of repression.

In their essential nature they are not merely diseases of the human body, but diseases of the social organism. The problem of their prevention or control involves not only questions of hygiene, but questions of morality—questions affecting the most intimate relations of our social life. This problem is most difficult and delicate and requires for its solution not only a thorough knowledge of existing evil conditions, but a largeness of ideas and a breadth of view which is not possible to those who look at it from the sanitary side alone. To correct these evil conditions there should be a union of all the social forces which work for good in the community.

THE NEED OF SUCH A SOCIETY.

That there is a need, and a most urgent need, for such an organization is abundantly evident from a consideration of the following facts:

It is now generally recognized that the class of diseases comprehended under the general term *venereal*, together with alcohol and tuberculosis, constitute the three great modern plagues which afflict humanity. Tuberculosis has been subjected to sanitary control, leagues have been formed against alcohol, and legislative aid has been sought through high-license and other restrictive measures to limit its evil influence, but the venereal plague is practically ignored and, in this country at least, its ravages are unchecked and apparently unnoticed.

THE MAGNITUDE OF THE VENEREAL PERIL.

The significance of syphilis as a social danger has long been appreciated by the medical profession. Years ago Prof. Gross declared that "a greater scourge than yellow fever, and cholera and smallpox combined is quietly installed in our midst, sapping the foundations of society, poisoning the sources of life, rendering existence miserable, and deteriorating the whole human family." According to Sir Thomas Watson, "it counts its victims not only in the ranks of the vicious and self-indulgent, but among virtuous women and innocent children by hundreds and thousands." When this was written, less than a generation ago, it was not known, even by the medical profession, that under the guise of what was considered a simple local disease of the urethra there lurked an infection which, in respect to the character and sum total of its dangers, is a greater curse to the human family than syphilis. Modern science has shown us that gonorrhea, which is regarded by the bearer as of no more significance than a common cold, which is treated as a joke or with the contempt of ignorance, is the greatest social pest of the age.

EXTENSIVE PREVALENCE.

Since these diseases are not subject to official registration the amount of venereal morbidity in this country does not admit of mathematical expression. In Europe it has been estimated by a distinguished authority that fully 75 per cent. of the adult male population contract gonorrhea, and that from 10 to 15 per cent. have syphilis. Assuming that we are a more virtuous people than those of Europe, it would be a most conservative estimate to say that the morbidity from both these diseases would represent 60 per cent. of the adult male population. Venereal morbidity is larger in urban than in rural populations, but everywhere its incidence falls most heavily upon the young.

It is a fact worthy of consideration that every year in this country 770,000 males reach the age of early maturity—that is, they approach the danger zone of initial debauch. It may be affirmed that under existing conditions at least 60 per cent., or over 450,000, of these young men will become infected with venereal disease—infallibly infected—if the experience of the past is to be accepted as a correct criterion of the future. Twenty per cent. of these young men will become infected before their twenty-first year, over 60 per cent. before their twenty-fifth year, and more than 80 per cent. before they pass their thirtieth year. This computation is not based upon loose conjecture, but upon carefully compiled statistical evidence. No allowance need be made for the incidence of mortality, since this is more than compensated for by the influx of young immigrants. The census of 1900 gives over 787,000 males thirty years of age.

These 450,000 infections, be it understood, represent the venereal morbidity incident to the male product of a single year; each succeeding group of males who pass the sixteenth year furnishes its quota of victims, so that the total morbidity from this constantly cumulative growth forms an immense aggregate.

The pathological importance of these diseases is to be measured not only by their effects upon the individual, but upon the family and the race.

EFFECTS UPON THE INDIVIDUAL.

The large proportion of individuals infected by venereal disease get well, some of them die, many of them suffer for years or during their entire life from its consequences.

Syphilis is a far more serious disease than was formerly supposed. Every year adds to our

knowledge of the number, variety, and gravity of its far-reaching complications and especially its morbid determinations to the internal organs most essential to life. Many affections of the brain, the cord, the liver, the heart, and the arterial system have their origin in syphilis. Of all the internal organs the brain is the most frequently affected by syphilis, and paresis is the most common termination. While syphilis, in the adult, is not a frequent cause of immediate death, the changes set up in certain organs or systems of organs are often the essential cause of death at a more or less remote period. Syphilis kills people to-day as it did in the 16th century.

Gonorrhea is an infection which, in addition to its local inflammatory complications, which often render the individual sterile, is capable of causing constitutional complications of a serious or even fatal character—such as deforming and incurable inflammations of the joints, pericarditis, meningitis, peritonitis, etc. The undeniable and scientifically demonstrated danger of gonorrhea is especially manifest in its serious effects upon the pelvic organs of women. It is the most common cause of inflammatory affections peculiar to women, which ruin her health, extinguish her conceptional capacity, and condemn her to a lifelong invalidism or the sacrifice of her reproductive organs to save her life.

The chief significance of these diseases as a social danger arises from the fact that they specifically affect the organs of generation—they damage or destroy the functions through which life is perpetuated, and thus defeat the social aim of marriage.

EFFECTS UPON THE FAMILY.

Pinard found that in 10,000 consecutive cases of miscarriages or abortions, 42 per cent. were caused by syphilis; the remaining 58 per cent. due to all other causes combined, artificial or otherwise. The destructive effect of syphilis upon the offspring is still further manifest in children stillborn at full term or who die shortly after birth. The mortality from hereditary syphilis ranges from 60 to 86 per cent., while those who survive are affected with various organic defects and degenerative changes which unfit them for the battle of life. If they reach maturity and marry they may transmit to their descendants—the third generation,—the same class of organic defects which they have inherited.

It has been computed that at the very lowest estimate, hereditary syphilis kills every year in France alone, 20,000 children, which represents 7½ per cent. of the mortality from all causes combined. It may be said that it is better that these children should die than survive as a race of inferior beings; it is to be remembered, however, that but for the fact of syphilis in the parents these children might have been born in conditions of vitality and physical vigor.

Gonorrhea is an even more potent factor of depopulation than syphilis, from its greater prevalence and more frequent introduction into married life and its inhibitory influence upon the conceptional capacity. It is computed that 50 per cent. of gonorrheal women are absolutely sterile, and that gonorrheally infected men are responsible for 20 per cent. of sterile marriages, when the sterility is not of choice, but of incapacity.

While gonorrhea is insusceptible of hereditary transmission, the child born of an infected mother is exposed to inoculation of the eyes with the virus resulting in the terrible affliction of blindness. Eighty per cent. of the blindness of the newborn is caused by gonorrhea, while it is computed that from 20 to 30 per cent. of blindness from all causes is due to gonorrhea.

FREQUENCY OF MARITAL CONTAMINATION.

The amount of venereal morbidity in married life is an unknown and unknowable quantity. Thousands of married women are infected without knowing or even suspecting the name or nature of the disease. The insidious character of the infection, especially of gonorrhea, favors dissimulation, and when known, every motive—pride, self-respect, shame—prompts to its concealment. It may be a startling statement, but nevertheless true, that there is more venereal infection among virtuous wives than among professional prostitutes in this country. Noeggerath stated that of every thousand men married in New York 800 had latent gonorrhea from which their wives became infected. Admit that this is an exaggeration—a gross exaggeration, even—say 8 per cent. instead of 80 per cent.; of the 16,000,000 married women in this country 8 per cent. would give over one and a quarter million infected from gonorrhea alone.

Unfortunately, the diseases of vice when transplanted to the bed of virtue develop their worst effects. The function of marriage is to create life, and in fulfilling this function the individual danger of the disease, especially of gonorrhea, is greatly accentuated. Pregnancy often transforms a latent and hitherto inoffensive gonorrhea into an intensely virulent infection, and the process of parturition opens the way to its upward ascension to a vital organ—the peritoneum—with results dangerous to life.

We are accustomed to recommend marriage to young men as the surest preservative against venereal infection. Can we with a clear conscience recommend to young women marriage with men who have led dissipated lives? Surely there is something rotten in a social system which places no restriction upon that individual liberty which permits men to poison their wives with venereal disease—which throws no sanitary safeguard around that relation which society has instituted for its own perpetuation. Certainly there can be no severer arraignment of that false system of education which directly fosters, and even renders compulsory, the ignorance which is largely responsible for these social crimes.

It cannot be gainsaid that the vast majority of infections in married life are effected through

ignorance—the opinion of all physicians who have had much to do with this class of cases is concurrent upon this point. The average man is not a criminal—he does not wreck the life and health of his wife and children knowingly and wilfully. In most cases he does it through ignorance of the nature and terrible consequences of his disease—ignorance of the prolonged duration of its contagious activity and, especially, ignorance of the fact that it is often infectious after apparent cure.

REMEDIAL MEASURES.

The cardinal principles of prophylaxis are, (1) To preserve the healthy from infection; (2) To prevent those already infected from infecting others.

It is the consensus of opinion among those who have studied this subject that a general diffusion of knowledge respecting the dangers, individual and social, of venereal diseases, their modes of communication, direct and indirect, would constitute the most efficient means of prophylaxis. This knowledge would be of inestimable benefit to the young in preventing ignorant and reckless exposure to dangers which many of them do not even know exist. Of the 4,000,000 or more of males in this country, between the ages of sixteen and twenty-one years, how many have received even the most elementary instruction in the physiology of the organs of generation? These young men are launched into the world without any knowledge of the hygiene of the sexual function or the dangers which attend its irregular exercise. They have been taught nothing of the diseases which are almost inseparable from commerce with bad women, or of the serious consequences to their health which those diseases may entail. It is believed by medical men who are most competent to judge these questions that ignorance is responsible for a large proportion of infections among the young, and that education would preserve thousands from exposure.

To whom this education should be addressed—what should be its scope or extent, and how, or through what agencies, it should be imparted—are subjects for consideration by the proposed Society. As regards the latter point, it might be assumed that this enlightenment should come through the agency of the medical profession. But the physician's opportunities for this educational work are comparatively restricted. He rarely comes in contact with the young man except in his capacity as a patient, after the harm is already done. So far as concerns the vast army of the working class and the poor who are treated by public charity, he practically never sees them except in the crowded classes of the dispensaries. The mode of this education cannot be individual, it must be collective and conveyed through means of lectures, conferences, tracts, or circulars. The physician cannot organize popular lectures; he may write papers exposing the dangers of venereal diseases, but they never reach the general public.

The proposed Society should be a centre for the diffusion of this enlightenment; it should be an influential force in effecting a reform in an educational system which now neglects all instruction in the hygiene of one of the most important functions of the body; it should propagate the idea that this hygienic education forms the most essential part of the training of the morals of young men.

Whatever may be the value of education as a preservative against exposure to infection, it will certainly constitute a valuable prophylactic measure against the introduction of these infections into marriage. Medical men now look upon certain marriages as moral crimes. When the plea of ignorance can no longer be invoked to shield those who carry disease and death into their families they should be declared legal crimes, involving not only civil but penal responsibility.

In fulfilling the second indication, the most valuable prophylactic measure is the prompt sterilization of sources of contagion by efficient treatment. The object is to cure as many as possible of those infected in order to sterilize the greatest number of foci. To accomplish this object the treatment should be gratuitous and available to all—not so much in the interest of the individual as in the interest of others he might expose to infection. Without entering fully into this subject, it may be said that the provisions for the treatment of this class of sufferers are notoriously inadequate, restrictive, and not adapted to the nature of the disease. Venereal patients are debarred entrance into our general hospitals, and discriminated against in various ways.

One or two gross abuses growing out of the insufficient hospital accommodations in this city may be briefly referred to. Of the thousands of respectable married women in this city infected with syphilis by their husbands some require hospital care; they can be received only in the female venereal ward of the City Hospital; they are compelled to inhabit the same room, sleep in beds side by side with the lowest and most abandoned prostitutes. It sometimes happens that a young girl who has taken only the first step in the downward path, and who, in being robbed of her virtue has lost her health, is compelled to go to the hospital; she is subjected to the close companionship and demoralizing influence of women old in vice, who are adepts in the arts of proxenetism. This is not the worst; young girls under fifteen years of age who come under the care of the "Society for the Prevention of Cruelty to Children," when found diseased, usually from criminal assault, are placed in this same ward and detained until they are pronounced cured. A female venereal ward has been termed *"un bouillon de culture pour la prostitution."* This society is not to blame for this practical perversion of the object for which it was founded, since the city affords absolutely no other provision for the treatment of these cases.

There are many social conditions which favor

the spread of these diseases — many of them requiring for their correction the intervention of the Administrative authorities, which would properly come within the scope of the Society's work. They are many-sided questions, and require many-sided minds to deal with them wisely and effectively.

ATTITUDE OF SOCIETY.

In the presence of this peril which so seriously menaces the public health and is fraught with such momentous consequences to the family and the race, the social forces are apathetic and inactive. Society does not seek to deliver itself from this evil, its only preoccupation is to cover up and conceal, to shut its eyes to its existence. From the mistaken idea that these diseases are always contracted through voluntary exposure and bear the stamp of immorality, their victims are without the pale of public sympathy or public protection. The public does not know that the immense majority of infections occur in the young, the inexperienced, and the irresponsible through ignorance and lack of moral training; it has no conception of the number of innocent women and children who are infected in the marriage relation.

It will be seen, then, that the diseases which it is the object of this association to prevent are preeminently Social Diseases—they affect the dearest interests of society, they enter into the most sacred relations of human life, they seriously menace the welfare of the family and the future of the race, they constitute a social danger of the greatest magnitude. They are diseases from which society suffers, and yet society views them with indifference, while the medical profession regards them with the deepest concern, and seeks to limit their spread. But the medical profession recognizes its inability to cope successfully with conditions which lie entirely without the sphere of sanitary influence or control.

We ask members of the laity—whose position in the community commands respect, whose opinions carry weight, who can influence public sentiment, institute educational reforms and secure needed legislation—to cooperate with the medical profession in forming a league against this Social Peril. This movement, which has for its chief objects the preservation of the youth of this country from ignorant exposure to infection and the safeguarding of marriage from the desecration of loathsome and dangerous diseases, appeals to that humanitarian instinct which prompts protection to the irresponsible ignorant, as well as the innocent and helpless members of society.

66 West Fortieth Street.

City Hospital for Homeopaths.—A bill has been introduced into Councils providing that a site at Twentieth street and Lehigh avenue be set aside for a department of the Philadelphia Hospital to be conducted by the homeopathic school. Action on the bill cannot be taken until after the summer recess.

THE MANAGEMENT OF OCCIPITOPOSTERIOR POSITIONS OF THE VERTEX.

BY JAMES D. VOORHEES, M.D.,
OF NEW YORK;
ASSISTANT ATTENDING PHYSICIAN TO THE SLOANE MATERNITY HOSPITAL; LECTURER IN OBSTETRICS AT THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK.

My object in selecting this title for a paper is not to add anything new to what is already known of occipitoposterior positions, but to corroborate and emphasize many of the recent statements made for their management from the standpoint of hospital and private practice.

In the first place there is a great discrepancy in the frequency with which these positions are encountered by various observers. Most writers estimate 70-75 per cent. of all vertex cases as primarily L.O.A., 20 per cent. R.O.P., 4 per cent. R.O.A., and only 1 per cent. L.O.P. I do not believe that these figures are correct. Before we can obtain their relative frequency we must be positive of the position of the head at the beginning of labor, as one who examines only during the second stage will class many cases anterior which started originally as posterior positions. The hospital statistics, which I have collected, show that primary posterior positions occur in about the proportion given above. Taking at random a thousand vertex cases from the records of the Sloane Maternity Hospital, I found 194, or a little less than twenty per cent. designated as primary occipitoposterior positions, but, as over one-half of the thousand cases were admitted in labor, the percentage should, in reality, be much higher. Again 341 cases were indexed as L.O.T. or R.O.T. positions. A great many of these probably also started as posterior positions, but had not completely rotated, so that these hospital figures are far from being correct. Right here I might state, on the other hand, that we should add both of these positions (L.O.T. and R.O.T.) to the four ordinarily given, for undoubtedly a goodly number of vertex cases start in this manner, not only where there is a relative flattening of the brim of pelvis, but also where the pelvis is normal or even justo-major in dimensions.

Another fact especially brought out in these hospital statistics is the relative frequency of right and left posterior positions. The ratio is given in text-books as 20 to 1, but in this series of 1,000 cases it is found to be 109 to 85, or almost equal in number.

Probably from one's own private practice, where cases are more carefully watched and a diagnosis of position is usually made shortly before and always at the beginning of labor, can we get at the true figures. The only difficulty is obtaining a large enough series from which to make general deductions. In the first 100 vertex cases, occurring in my private practice, I have recorded 27 (27 per cent.) R.O.P. and seven (7 per cent.) L.O.P. positions, showing that the latter occurred less frequently than at the Sloane Hospital, but I also recorded 15 cases (or 15 per cent.) starting as L.O.T. and only six (or 6 per

cent.) as R.O.T., and it is more than likely that some of the former started posteriorly.

Whatever the value of these figures, they show at least that we should regard L.O.T. and R.O.T. as primary positions of the vertex, and that left occipitoposterior positions occur more frequently than is ordinarily imagined.

The diagnosis of these positions can readily be made. If in last two weeks of pregnancy the head has not entered the pelvic inlet, or does not even dip therein, we should suspect that the occiput is posterior, even without carefully examining for an exact position. Yet this riding high of the head, of course, may be caused by a disproportion between the size of the head and the size of the brim of the pelvis. My experience has taught me that only an excessive amount of abdominal fat or liquor amnii will render unreliable the signs obtained before labor by abdominal palpation and auscultation. Vaginal examination will clinch the abdominal diagnosis, provided the cervix is sufficiently dilated to permit one to feel the sutures and fontanelles.

At the time of labor, when the pains occur at short intervals, or the uterus is tightly contracted about the child, abdominal examination may fail to give positive results. In such cases the vaginal examination alone must be relied upon.

There are certain men who claim that enough can be obtained from the abdominal signs and the frequency and character of the labor pains to make vaginal examinations unnecessary, as they fear the possibility of infection. Although admitting that indiscriminate and frequent vaginal examinations are to be condemned, I believe that many of us are not satisfied as to the position, the flexion of the head, its descent, the degree of molding, and the consistency and dilation of the cervix unless a vaginal examination is made not only early in labor, but also later, when occasion arises. Even then one is not always sure of the state of affairs. Take, for example, cases where there is a very thick caput succedaneum, an accessory suture, a Wormian bone, or a false fontanelle just in front of the posterior fontanelle. Under such conditions, we are often not only justified but compelled to do more than to make a simple vaginal examination. We must carry the hand into the vagina and up into the uterus before we can make a positive diagnosis preparatory to instituting the correct measures to facilitate or to terminate a protracted labor.

As prophylactic measures in the management of occipitoposterior cases, postural treatment and external manipulations either before or at the beginning of labor can be tried, but how much success will be achieved by these methods is very uncertain. Nevertheless, we ought to take advantage of them, for nature often only needs the slightest aid to work wonders. The correction of the malposition may be aided by keeping the patient on her feet by moderate out-of-door walks before labor and about the room during the first stage of labor. I also believe that small doses of quinine and strychnine, either used singly or in combination, for one to three weeks before labor, or during the first stage, may act as auxiliaries by strengthening the pains.

Before anyone undertakes the operative delivery of an occipitoposterior position, he should make himself thoroughly familiar with the normal mechanism. He should not be alarmed simply because he has such a position to deal with, since a large percentage, some observers say as high as 90 per cent. rotate anteriorly spontaneously.

In order that this anterior rotation may occur a number of conditions must be fulfilled: (*a*) The head must not be too large for the pelvis, nor the pelvis too small for the head; (*b*) the flexion must be good; (*c*) the pelvic floor must be resistant; (*d*) the uterine contractions must be strong.

I believe that a lack of this last condition is probably the most frequent cause for interference. The age of primiparity to-day is raised to a high average (thirty years or thereabouts), the high nervous tension of our city woman with her "hothouse" bringing up, and her inability to endure pain, together with the lack of self-control under it, demanding the early administration of chloroform, all tend to lessen our principal force—that of expulsion. The uterine contractions have a great deal to do in a posterior position. The head must be often molded into and through the brim, must be flexed, must be forced down to the pelvic floor, must be rotated through three-eighths of a circle; must be remolded through the outlet, and finally forced over the perineum. If the contractions are weak and inefficient these steps may not occur, and the accoucheur may be compelled to step in at any time.

Let us take the cases when we are called upon to assist either for the sake of the mother or child.

1. *An Occipitoposterior Position Above the Pelvic Brim.*—Before going into details as to the management of these cases, I wish to issue a warning against too early interference. I have seen many cases brought into the Sloane Hospital where forceps had been tried outside and failed, but where, a little more time having elapsed, as in transit in the ambulance, the head has engaged or descended well into the pelvis or rotated, so that labor has terminated spontaneously or with but slight assistance.

If the head is movable and high, the accoucheur must duly weigh all the conditions before he decides what to do. The plan of treatment which I would recommend when the pelvis is normal is as follows: Get first as complete a dilatation of the cervix as possible, then under deep anesthesia carry the hand into the uterus and manually rotate the occiput anterior. This can often be accomplished if the lower uterine zone is not retracted about the child. Then holding the head in position by the hand inside the uterus, and aided by an assistant making strong pressure on the fundus, apply the forceps to the sides of the head.

Often this anterior rotation will be brought

about in another way. By introducing both of the blades of the forceps posteriorly, one over the other, and in rotating them for a pelvic application, the head will rotate also, and the application will be cephalic as well. Rotation of the head by means of the forceps above the brim using force, however, is fraught with great danger to the mother and most often results in failure.

If, after rotating the head, and using moderate traction with the forceps, the head does not descend, or if the pelvis is found to be flattened, version would probably be the better operation, safer for both mother and child.

The cases which are the most trying are those where there has been a dry labor and the lower uterine segment is tightly contracted about the head. Here manual rotation is impossible and version absolutely contraindicated for fear of rupturing the uterus. These cases demand a patient and prolonged effort with the forceps, carefully watching the condition of the child. What must we do? We must drag the head through the brim and down to the pelvic floor in its posterior position before nature will help us, or before we can assist the rotation. The blades do not fit the head, the hold is insecure, and no matter what kind of a forceps is used there is a tendency to slip, especially when a fair amount of force is employed. One blade, if the position is R.O.P., holds only by the tip against the right side of the forehead, and the other blade grasps the left side of the occiput by its anterior edge. Consequently, to prevent this slipping, one must of necessity crowd the blades together, and so unduly compress the head. Again, even if we use axis traction forceps, there is considerable resistance on the part of the symphysis, the part of the head in front of the coronal suture impinging against it, and it necessarily follows that, when great force is required, this soft part of the skull is pushed up and intracranial lesions may result, so that the child is often born dead or dies in a few days. A symphyseotomy, or better, a Cæsarean section, would be the only method of getting it out alive in such cases, but we are unwilling at the outset to propose this operation without giving forceps a trial. Then it is too late. In some of the cases in which the child dies in attempting forceps, or is *in extremis* when we are called upon to deliver, craniotomy will become necessary.

2. The second group includes those cases where the head is engaged in the superior strait or is in the midpelvis. Sometimes the manipulation of pushing up the forehead and thereby increasing the flexion will allow the occiput to come down low enough during a pain to meet the resistance of the pelvic floor, and so start the rotation in this class.

When, however, the forceps is indicated, often under complete anesthesia, if the head is not wedged into the pelvis, in introducing both blades posteriorly the head will rise above the brim and, upon applying the blades, it will rotate with them, so that the posterior position is at once overcome and the forceps grasps the head cephalically. If the head is practically impacted in the pelvis, the blades must be applied to the sides of the pelvis. Usually, as the occiput strikes the pelvic floor, it rotates anteriorly spontaneously, or we can assist the rotation with the forceps by readjusting the blades from time to time with each advance until the occiput is anterior. This is especially the case when solid blades are used. There are a few cases, however, in which rotation will have to be effected as described in the next class.

3. This class includes the largest proportion of cases where the head is at the pelvic outlet with occipitoposterior. We ought not to think simply because of this abnormal position that all cases should at once be corrected. The great majority rotate spontaneously. Many others can be allowed to come through with the occiput behind, for although the prognosis for the child is supposedly worse and a larger anteroposterior diameter of the head comes over the perineum, serious damage is very rarely done. To illustrate, out of 104 persistent occipitoposterior positions in 5,000 deliveries at the Sloane Maternity Hospital, 55 were allowed to be born with the occiput behind, and only in four cases was the perineum slightly torn. Nine of these happened to be primiparæ, with fairly firm perineal bodies. Not that I recommend this to be the usual treatment in private practice. I simply wish to show that the outlook is not so bad after all when anterior rotation fails to occur.

Many cases can be manually turned with ease. Twenty-seven out of the remaining 44 cases in the above series were successfully treated in this way, although in four uterine inertia made the application of forceps necessary after anterior rotation had been effected.

How, then, shall we use the forceps when necessary?

In four ways: (*a*) Most cases will rotate while the blades, having been first introduced posteriorly one over the other, are being rotated for a pelvic or cephalic application as if the head were in an L.O.A. or an R.O.A. position. (*b*) Others can be rotated, using the first blades as a vectis, the left blade in an L.O.P. position, and the right blade in an R.O.P. position. Then introducing the second blade laterally for a cephalic application, one can hold the occiput in front and deliver in the usual way. This same method will apply to L.O.T. or R.O.T. cases—that is, where the occiput is caught half-way around and the flexion is poor. (*c*) In this set of cases the forceps is applied to the sides of the pelvis. After a few tractions the head either starts to rotate and we help it along a little, or we inaugurate the rotation with the forceps. With each advance we readjust the blades without removing them. The occiput gradually turns so that the sagittal suture is transverse, then the occiput passes beyond the transverse line and finally, as the head comes out under the pubic arch, it assumes a directly anterior position and is easily delivered. (*d*) There are a few cases, however, which we see now and then in hospital practice where the

head is wedged in the pelvic outlet, so that the above procedures will not succeed, and where a slight amount of force is necessary to obtain anterior rotation.

Some authorities recommend the straight-bladed forceps. Others use the ordinary forceps but with the pelvic curve reversed. By the former method we are rarely successful, and by the latter we run too much risk of injuring the mother's soft parts. The correct way to handle these cases when the first three methods fail is as follows: If the case is an R.O.P. position, regard it primarily as an L.O.A. position, and then introduce the blades in the usual manner, applying them to the sides of the child's head. Next, without force, carry the handles of the forceps to the left thigh of the patient. By this maneuver the flexion is increased and the tips of the blades are in the middle of the pelvic canal. Then, with little force, swing the handles downward, describing an arc of a circle. The head turns to an R.O.T. position first, and then, as the handles complete the arc, carrying them as far posteriorly as the perineum will allow, the occiput gets under the pubic arch. In this way the tips of the blades are still in the axis of the pelvic canal, not doing any harm. Now hold the head in position for two or three pains, with the pelvic curve of the forceps inverted, but using no traction. This is done to prevent the head from returning to its former position, and in order to allow the body of the child to rotate anteriorly to accommodate itself to the head. After we are sure the occiput will stay in front remove the blades. Many of the cases will now terminate spontaneously. If there is still delay, the forceps can be reapplied, and the delivery accomplished with ease. When one examines this method carefully, he will find that it is not so dangerous as he imagines, although it should only be used by a man skilled in the use of forceps. The neck of the child is not twisted beyond what it can safely stand, because the body will likewise rotate. The force used is not necessarily great, nor are the mother's soft parts injured if proper care is employed.

The Tucker-McLane solid-bladed forceps is the best variety for use in all the above methods, not only on account of the facility of introduction, application, rotation and removal, but also because they mark the child less.

In conclusion, let me say that the last method is not often necessary. It has been known at the Sloane Maternity Hospital for at least nine or ten years, yet in 104 persistent occipitoposterior positions in the series of 5,000 cases there, above mentioned, it was practised only seven times.

In my private practice, out of nine posterior positions with the head *low down* in the pelvis, needing assistance by the forceps, all were easily rotated anteriorly by the first three methods just described.

At the Sloane Maternity Hospital, in 1,000 vertex cases (8,000 to 9,098), 109 were R.O.P. positions; 85 were L.O.P. positions; 131 were R.O.T. positions; 210 were L.O.T. positions.

Of these 1,000 cases 523 were admitted in labor. Of the L.O.T. and R.O.T. positions 183 were admitted in labor.

In 5,000 cases (6,000 to 11,000), 104 were persistent occipitoposterior positions.

Fifty-five were allowed to be born occipitoposterior, but only in four was the perineum slightly torn, though nine were primiparæ; one child died, not counting the non-viable and very premature cases up to 7½ months.

Twenty-seven were rotated manually, and in four of these the forceps was subsequently applied; one perineum was torn and one child died; nine were primiparæ.

Nineteen were rotated by forceps, but only seven by the reapplication method; two were rotated using forceps as a vectis; three perinea were torn; five children died; 16 were primiparæ.

One child already dead—delivery by craniotomy.

Total deaths, children, eight (counting craniotomy case).

Total perineal tears, eight.

Private practice: In 100 vertex cases 27 were R.O.P.; 8 L.O.P.; 15 L.O.T.; 6 R.O.T.

1. Of the occipitoposterior remaining persistent above, at or in the brim, five required high forceps, two justo-minor pelves, two flat pelves. All of them rotated anteriorly on applying the blades.

2. At midpelvis, or just below: three required forceps, all rotated anteriorly in applying the blades.

3. At outlet: Two were rotated manually and then were born spontaneously; three were rotated manually and then the forceps was used; five rotated in applying or readjusting the blades; one rotated using one blade as vectis; six after normal rotation required the forceps. There were no deaths of children. There were six moderately torn perinea in the above forceps cases. (Two tears were due to rapid delivery to save the child.)

SCURVY IN INFANTS.[1]

BY WILLIAM FITCH CHENEY, M.D.,

OF SAN FRANCISCO, CAL.;

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, COOPER MEDICAL COLLEGE, AND PHYSICIAN TO LANE HOSPITAL, SAN FRANCISCO.

I HAVE recently seen in consultation two very similar cases of disease in infants; yet in each case the physician in charge frankly stated that the symptoms were new to him, and that he did not know how to interpret them. Having seen a number of such cases before, and feeling sure that the condition is a not uncommon one, I am prompted to call the attention of the profession once more to scurvy as it occurs in infants. My recent cases were as follows:

Case I.—Seen in consultation in Menlo Park, January 9, 1904; a male infant, aged eight months. For several weeks the baby's appetite had been failing and he had been growing more

[1] Read before the California Academy of Medicine.

and more restless and sleepless. Several times during these weeks his napkin had been stained with blood passed with the urine. Recently great tenderness had been noticed about both lower limbs, so that he screamed when raised or handled, or especially when his limbs were elevated to change his napkin. Finally, a few days previous to my visit it was observed that the gums about his two upper incisor teeth were swollen so as to nearly hide the teeth, were dark purple in color and bled when touched.

Case II.—Seen in consultation in Alameda, February 3, 1904; a male infant, aged thirteen months. This baby, so the mother said, cried violently whenever his legs were moved, as in putting on his shoes and stockings or changing his napkin; and had done so for eight or ten weeks before I saw him. He had gradually grown worse in this regard, so that now he would no longer sit up and could not lie in any position for any length of time without crying from pain. The mother knew of no cause, and the baby had been treated for a long time for rheumatism. He screamed violently when his legs were examined; both were found swollen from the knees down, markedly about the ankles and feet. The baby was found to have four teeth—two upper and two lower incisors; the gums about these were much swollen, so that the teeth were nearly hidden, were dark purple in color and bled when touched.

In each of these cases the symptoms meant scurvy and could mean nothing else. I observed my first case of this sort in July, 1895, and reported it in the MEDICAL NEWS, February 29, 1896, this case being, so far as I am aware, the first one reported from the Pacific Coast. Subsequently a collective investigation of the subject was made by the American Pediatric Society at its annual meeting in 1898; and to this report I contributed the history of three cases observed to that date. Including the two cases herewith reported, I have now seen ten cases of scurvy in infants.

Etiology.—The disease occurs mainly during the first year of life. It seems to be dependent in some way upon the food given; but it occurs in infants fed on many different kinds of foods, and does not occur in all infants fed on such foods. Most often infants who develop scurvy are taking some one of the proprietary foods. In my own cases, Mellin's food, Eskay's food, Horlick's malted milk and condensed milk have been the foods taken at the time the scurvy developed. But I have the records of many other infants fed on exactly similar formulæ, who never developed any sign of scurvy. No one has ever satisfactorily explained how the diet causes the symptoms, or what the substance is that by its presence in or absence from the diet might lead to the pathological changes observed. In other words, the exact cause of scurvy in infants is still unknown.

Symptoms.—These are quite characteristic and diagnostic. The most important are (1) *pain on movement of the lower limbs;* such movement, whether voluntary or due to handling, causes the infant to scream with pain; as a consequence the limbs are not used and they appear paralyzed; frequently, but not necessarily, the thighs or legs are swollen and brawny to the touch; more often along the shaft of the bone than at the joint. All of these symptoms are due to a greater or less degree of subperiosteal hemorrhage. (2) *Purple swollen gums.* This symptom occurs most often in infants that have teeth through the gum or about to appear, and involves only the gum about such teeth. It has been observed in gums that had no teeth through them; but not so often. The gum is so swollen as almost to bury the teeth, is usually dark purple, almost black in color, is spongy and softened and bleeds easily. (3) *Subcutaneous hemorrhages.* These resemble bruises or "black and blue" marks. In the first case I ever saw, in 1895, the infant had a typical "black eye." In another there was a large purple area over the buttock and thigh as if the baby had been beaten. Such spots may appear in any part of the body, and usually take the form of good-sized patches rather than of diffusely scattered purpuric spots. (4) *Hemorrhage from mucous membranes.* This may be from the mouth or throat; from the nose; from the bowel; or from the bladder—bloody urine had been one of the alarming symptoms in Case I, herewith reported. (5) *Anemia and Malnutrition* are usually complicating conditions, but in no way peculiar to scurvy.

Diagnosis.—Given an infant six months to a year old; a history that the legs are tender and the baby screams when they are moved—scurvy is always the most likely explanation. If on examination the gums are found swollen, discolored and bleeding; or if black and blue marks are discovered or have previously been seen by the mother on the baby's body, the diagnosis may be made with almost absolute certainty, especially if the infant is and has been for some time fed on one of the proprietary foods.

Differential Diagnosis.—The most frequent mistake made is to call the case *rheumatism.* It cannot be impressed too often or too strongly that young infants do not have rheumatism—at least it is so extremely rare that practically it may be left out of account; while scurvy, on the contrary, is not at all an uncommon ailment in the first year of life. The disinclination of the infant to use the limbs now and then leads to an erroneous diagnosis of *paralysis;* but paralysis never gives rise to pain and tenderness of the limbs as scurvy does; an examination will show that the loss of power is apparent rather than real. The condition of the gums described should always make the observer suspicious of scurvy; but I have once seen a case where the gums had been lanced, because their swollen, purple state was supposed to be due to difficult dentition. It is rare to see purpura hemorrhagica in the first year of life and no matter how many hemorrhages have occurred into the subcutaneous tissues and from mucous membranes, scurvy is always the more

likely cause in a young infant; besides the symptoms in limbs and gums are almost invariably coincident and complete the picture. Finally, an *injury* to the limb is often suspected, but rarely occurs in such young infants; for they cannot walk and have so little opportunity for traumatism.

Prognosis.—Scurvy is a disease in which proper treatment works a miracle. It has no tendency to spontaneous recovery; but when recognized and given the proper care, improvement is immediate and cure is surprisingly rapid. No other disease affords the physician a better prospect for brilliant results.

Treatment.—Just three measures are indicated for the cure of scurvy: (1) Discontinue the proprietary food. Substitute for it a mixture of fresh milk diluted with water or with oatmeal water. (2) Give fresh orange juice, in dose of one or two teaspoonfuls three times a day. It is surprising how babies with scurvy take to this and seem to enjoy it. (3) Give freshly expressed beef-juice, squeezed from rare steak, in dose of one or two teaspoonfuls three times a day. (4) Give no drugs at all.

All of my cases have been treated in this simple way. In Case I, herewith reported, every symptom had vanished in four days after treatment as above. In Case II, after ten weeks of suffering the baby was absolutely well in one week. The recognition of scurvy is easy when only we realize that such a disease exists; the treatment is so simple that we feel almost ashamed to take the credit for the good it accomplishes; and the change we are able to effect at once in a disturbed and discouraged household is so magical that scurvy in infants becomes really the most fortunate disease the physician can ever hope to meet.

MEDICAL PROGRESS.

MEDICINE.

Diminution of Liver Dulness.—It is now well recognized that diminution or even absence of liver dulness is not a reliable sign of the pressure of free gas in the peritoneal cavity. S. V. Pearson (Med. Chron., March, 1904) has carefully examined 140 cases of ulcer of the stomach and finds that 33 per cent. of that number have shown a considerable decrease in the liver dulness at some time during their stay in the hospital. In none had perforation occurred. He does not believe that cases of gastric ulcer are particularly more liable to show this decrease in dulness than other diseases. This number did not include any in which the decrease was due to emphysema or other lung conditions nor any in which the diminution was at all ambiguous. Complete absence of dulness was present in three or four cases of simple gastric ulcer. The explanation of this phenomenon is not at all clear. It is not associated with any marked degree of distention, nor with pain or tenderness. It has been suggested that this condition was due to a distended gut getting up in front of or behind the liver, marking the normal dulness or actually pressing the liver upward. It has been found that the great majority of cases are in young females, and this is the case, no matter what the nature of the associated disease. This marked decrease in dulness also frequently occurs very commonly at the time of the monthly period whether it be associated with pain or not. Again, the amount of food in the stomach may have some influence, but the complete explanation of the condition is by no means satisfactory.

Diazo and Widal Reactions in Typhoid Fever.—It requires a wide experience and careful observations to determine the true value of many of our clinical tests, and, therefore, a great diversity of opinions still exists in regard to the importance of positive results in the above tests. C. B. Ker (Practitioner, March, 1904) believes that the diazo-reaction of Ehrlich may be of considerable assistance in the diagnosis of typhoid because it is usually present from the fourth to the sixth day, when many of the other signs are still absent. It is, however, usually present in several other diseases, being almost invariably present during the eruptive stage of measles, but this is, of course, of very little importance. It seems to be always present in typhus and is usually found in miliary tuberculosis. It is occasionally present in lobar pneumonia and more rarely in bronchopneumonia. The value of the test is rather its absence than its presence. A case of continued fever which does not give the reaction between the sixth and twelfth days is in all probability not enteric fever. On the other hand, if it is present, it is necessary to exclude the eruptive fevers, miliary tuberculosis and pneumonia. In regard to the Widal reaction there are still a great many physicians who seem somewhat skeptical concerning the dependence which should be placed upon the significance of its presence. No doubt the reason for this is that the results which are frequently obtained follow methods which are not sufficiently skilful and careful. It requires a great deal of painstaking work by an experienced man to obtain valuable results. The author uses a dilution of one to thirty, but most authorities now consider the reaction positive only when dilutions of one to fifty are used. It may now be safely said that a positive reaction means that the patient has enteric fever at the moment or else has suffered from it previously. A negative reaction during the first two weeks means little or nothing. If it is still negative in the third week there is a strong presumption against typhoid and if it remains negative in the fourth week the idea of typhoid may be dismissed.

Hypodermoclysis in Pneumonia.—In spite of all the innovations which have been made in the treatment of pneumonia the death rate has been very little changed during the past three or four decades. Statistics, however, in such a disease as pneumonia, in which so much depends upon the age, the previous habits and condition of the patient and the "genus epidemicus" are not only not infallible but often misleading. F. P. Henry (Med. Chron., Feb., 1904) who was the first to use hypodermoclysis in the treatment of pneumonia, believes that it is theoretically indicated in every case of pneumonia although he does not employ it in many mild cases. It dilutes toxins and favors their elimination; it preserves the alkalinity of the blood, which is one of the most important properties of the vital fluid and, finally, certainly tends to prevent the formation of heart clot, which the writer believes to be a frequent cause of death in pneumonia. The solution employed contains 50 grains of sodium chloride to the pint of distilled and sterilized water. He uses a large syringe or chest aspirator, the action being reversed, and injects from eight ounces to a pint once a day.

Tardy Abscess of the Liver.—Attention is called to the fact that tropical dysentery may be followed by hepatic abscesses a long time after the latter has sub-

sided, by P. K. Pel (Berl. klin. Woch., April 4, 1904). He reports three cases where the lesion came on at varying periods from eleven to twenty years after the dysentery had cured and after periods of good health. There was no other cause apparent for the production of such an abscess except the former attack of dysentery and idiopathic abscesses are extremely rare. The author thinks that encapsulation of some small pus focus had taken place, which had remained quiescent for years, but that at the periphery a certain number of microbes had remained alive. Such encapsulation has been proved in the case of typhoid bacilli, where in one instance they were found encapsulated in a focus in the tibia fifteen years after recovery from typhoid.

Toxic Agent of Cholemia.—Icteric patients sometimes develop an alarming series of cerebral symptoms which usually end in coma and death. The direct cause has frequently been a matter of speculation and it is as yet undecided whether the bile pigments, bile acids or the loss of hepatic function are at fault. A. Landau (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 5 and 6) noticed a close resemblance to diabetic coma and concluded that the whole condition is an acid intoxication. The common bile duct was ligated in a number of rabbits and the blood titrated every day until death, which generally occurred on the fifth or sixth day. The alkalinity gradually diminished day by day, but not to a sufficient degree to account for the symptoms on the basis of an acid intoxication. The amount of carbon dioxide was also found considerably below normal. Since animals with much less alkali have been known to live for days, probably other facts bring on the fatal issue.

The Value of the Phonendoscope.—The improved phonendoscope has been thoroughly tested by D. Sehrwald (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 5 and 6), and found by him to possess no advantages over the ordinary stethoscope. As resonator it can only magnify one particular sound, while all the others are diminished in intensity or suppressed altogether. The complex sounds of the heart and lungs are thus reproduced very imperfectly, and their character considerably altered. Even the use of the valve on the resonator does not improve matters, for if opened, the resonator will lose its property as sounding board and fail in transmitting low sounds. Moisture and hairs interfere considerably. In employing the phonendoscope for auscultatory percussion, one generally obtains oval or circular figures, whose size does not depend upon the organs percussed but chiefly upon the moisture and tension of the skin. A heart-shaped figure can thus be percussed after the heart is removed from the thorax and in other places remote from the heart. The common stethoscope does not give such loud sounds, but is much more satisfactory.

Diagnosis of Gouty Deposits in the Ears.—W. Ebstein (Deutsch. Arch. f. klin. Med., Vol. 80, Nos. 1 and 2) finds that in patients suffering from gout or rheumatism, nodules are occasionally discovered in the auricle, which at first sight impress one as tophi, yet are situated in the cartilage and do not contain urates. They are sometimes cysts, sometimes cartilaginous excrescences and, though occurring most often in gouty individuals, do not justify the diagnosis of gout with the same certainty as in the case of uratic deposits.

SURGERY.

Anesthesia in Abdominal Surgery.—When we come to the selection of anesthesia in celiotomy, it will, in the majority of cases, be one between ether pure, with nitrous oxide, with oxygen or chloroform, but J. J. G. Williams (Am. Jour. of Obstet., March, 1904) thinks that by most operators ether alone will be chosen. Spinal anesthesia with cocaine has been tried and found wanting. The author gives the following reasons for preferring ether: (1) It is nearly always possible to procure a fresh supply. This is not true of chloroform. (2) Ether is safer, there being one death in 10,000 cases, while chloroform gives a mortality of one in 2,000 administrations. (3) The patient can be placed under ether nearly and quite as quickly and quietly as with chloroform. (4) With ether one can keep the patient pretty much in the stages desired; with chloroform, the author has seen them go quickly from sensation of pain to deep narcosis. (5) When one is compelled to place the anesthesia in the hands of a layman or, as has frequently been done, the domestic servant, ether is safer. Chloroform is likely to kill early, during the first few inspirations or when struggling occurs. (6) When organic heart disease is present, ether, for a time, stimulates the heart. (7) Ether has been administered to alcoholics, those with pulmonary tuberculosis and with pathological kidneys, and in these cases it is as safe as any general anesthetic, if not safer. When the patient has been anesthetized, there are two methods of continuing the administration during the operation: (1) The anesthetic may be given by dropping one-half to one dram over the nose-tip every minute or so. (2) Use the "drop method" as in giving chloroform, allowing one drop to slowly follow another. Always withdraw the anesthetic when tapping a large cyst or ascites, and when removing bulky fibroids, keep it withdrawn until the patient shows signs of returning consciousness.

Subsequent History of Gall-bladder Cases.—Question blanks were sent to the last 350 cases of gall-bladder disease operated by H. Kehr (Münch. med. Woch., April 5, 1904), exclusive of carcinoma, to determine the results and after-effects of the operation. Most valuable statistics were obtained, which prove that the relief is generally permanent and the danger slight, with increased experience. Thus stones were left behind in only 2.5 per cent., but the operator was aware of this in more than half, where the relation of the biliary ducts was so complicated that a radical procedure could not be restorted to. Most of the others passed the stones spontaneously and are free from symptoms, and only one case necessitated a second operation. In 350 cases only one mucous and one biliary fistula remained behind and herniæ were encountered in only 11, where extensive suppuration required an elaborate tamponade. Colic, due to adhesions, was observed twelve times, due to inflammation five times; in these 17 cases the appendix was removed five times, in three a pyloroplastic and in two a gastroenterostomy was performed and one suffered from hepatoptosis. Care must be taken not to mistake subsequent renal colic for recurrent biliary pain, since both conditions may exist together.

Gangrene of the Hollow Viscera.—Mesenteric thrombosis, while rare, has been referred to by numerous authors. Nevertheless, like many other obscure abdominal conditions, there is certainty that its presence has been overlooked in many cases and that it is much more frequent than usually supposed. Roswell Park (Ann. of Surg., April, 1904) calls attention to the most significant symptoms. They are as follows: (1) Sudden onset. The pain begins instantly and is apt to be overwhelming in its character. It cannot be quieted by an ordinary opiate. There are, however, cases which have run their course without any appreciable pain. (2) Diarrhea. This is usually an early symptom, evacuations being profuse and often bloody. (3) Obstructive symptoms. These are sometimes those of the ileus, sometimes of constipation. (4) Vomiting. This usually occurs early, the material being bloody and early fecal. (5) Rapid pulse. This may run as high as 140. (7) Subnormal temperature. (7) Meteorism. (8) Ab-

dominal rigidity. It is said that when the inferior mesenteric artery is involved, tenesmus becomes a prominent characteristic. A differential diagnosis has first to be made between the perforating ulcer of the stomach or duodenum; 15 per cent. of gastric ulcers perforate. Second, acute obstruction. This includes all rarer forms of internal hernia. Third, pancreatitis. This may very closely simulate mesenteric inclusion, the suddenness of the disease in the latter case being the only distinguishing feature. Fourth, acute splenic infarct. This is naturally a difficult condition to differentiate from obstruction to one of the mesenteric vessels, because it is usually caused by embolism of the splenic artery. Fifth, acute appendicitis. In every detail except in degree, acute appendicitis simulates the greater disease under consideration. Sixth, acute cholecystitis. Here there is usually a history of previous disease of gall-stone colic. Seventh, extra-uterine pregnancy. Eighth, intrathoracic lesions; left-sided pneumonia is one of these. The only recorded case of mesentery exclusion not proving fatal is recorded by Chiene. The branches of the mesenteric arteries were found filled with the injecting fluid of the dissecting room, their main trunks, however, were blocked by an old embolic process. The blood reached the mesenterics through the left and middle colic vessels. These cases seem to be beyond the realm of hope even if the very earliest surgical attention be given them. Nevertheless, in view of the extraordinary length of gut which has been successfully resected, there may be cases of mesenteric embolism of a mild degree which can be saved by early intervention. At all events, no time should be wasted in speculation as to the character of the lesion, it being evident that no such case as would be lost without an operation would be lost in consequence of it. Of these cases, as of most others in the hands of competent men, it should be said that they die in spite of operation, not because of it.

Diagnosis of Frontal Sinus Osteoma by the X-Rays.—The difficulties attendant upon the diagnosis of this condition ought to be simplified by the employment of the Roentgen rays, but thus far no skiographs of the lesion have been published. G. Perthes (Archiv f. klin. Chir., Vol. 72, No. 4) reports a case where the X-rays proved to be of the greatest importance both as regards the diagnosis and the determination of the site of operation. By the removal of the growth, the malposition of the left eye was corrected, the headaches and other symptoms disappeared. Without the rays it would have been impossible to recognize the presence of a bony tumor on the roof of the orbit, which was displacing the bulb. No elevation could be detected on the forehead and the tumor might as well have been an exostosis. The skiagraph taken in two planes showed that the growth extended 4 cm. above the roof of the orbit and beyond the median line to the other side.

Thrombosis of Superior Mesenteric Artery.—An interesting case of thrombosis of the superior mesenteric artery, in which an early operation was done without, at that time, a full knowledge of the cause of the trouble, is reported by H. G. Mumm (Interstate Med. Jour., April, 1904). As in almost all instances of this condition, the case presented the signs and symptoms of acute intestinal obstruction and the operation was done to relieve it. No obstruction, however, was found and the small intestine showed a rather marked congestion and in some places there was a particularly tight, tonic, muscular contraction present, rendering the caliber of the small intestine extremely narrow. This contraction would involve several inches in length of the intestine in various portions with intervening parts of the gut normal. Then the contracted portion would relax and the tonic spasm of the muscular wall occur in other parts, not traveling in continuity. After the operation, gas and feces were expelled by rectum but the constitutional symptoms and signs grew worse and he died in four days. Autopsy showed a gangrene which began just below the duodenum and extended throughout the small intestine and involved the cecum and about one-half the transverse colon. The superior mesenteric artery was found closed by a thrombus which began about one-half inch from its origin from the aorta. The other abdominal organs showed no important changes. No sufficient cause could be established for the thrombosis in this case, for the man was only thirty-six years old; there was no history of syphilis, no heart lesion, no atheroma, no embolus elsewhere. A slight twist of the mesentery upon itself was, however, found, and it is possible that sufficient injury occurred from it to determine the site of the beginning thrombosis. The author is inclined to the belief that many of the so-called cases of embolism are really instances of thrombosis, probably due to some distinct injury.

Surgical Treatment of Goiter.—A large number of parenchymatous goiters, successfully treated during the past fifteen years by a combination of internal and external methods, are reported by C. H. Mayo (Jour. Am. Med. Ass'n, April 23, 1904). He also has operated on 110 cases for the relief of some type of thyroid tumor. Of these, 34 were for exophthalmic goiter, with six deaths. He prefers the Kocher collar incision as giving the greatest exposure and the least scar. He precedes anesthesia with morphia subcutaneously and uses ether by the drop method, unless there is extreme dyspnea or marked exophthalmic symptoms. In such cases he uses cocaine by injection. The exophthalmic cases which recovered from the operation were all benefited within three months; in only 25 per cent. was the improvement partial, the exophthalmos being slow to disappear. None of those who lived were made worse and those in whom death occurred were the most severe types of Graves' disease, with tachycardia of from 130 to 150.

The Appendix and Typhoid.—The prophylaxis in perforative peritonitis from typhoid fever is the pivot on which every effort in treatment should revolve, until either the cause is removed or accuracy in diagnosis has enabled the clinician to recognize the perforative stage, as prompt interference after perforation has taken place has evidenced any marked lowering in the mortality table. The appendix is the seat of perforation in about five per cent. of all cases, and L. J. Hammond (Jour. Am. Med. Ass'n, April 16, 1904) claims that in addition to this there is a large number of cases occurring in the ileum and ascending colon that can be directly traced to preexisting disease of the appendix. In support of this he reports two cases, where the tension from bands of adhesions between the appendix and other parts of the gut caused rents in the ulcerated patches. He believes that where the appendix has been the seat of a previous inflammation a disease like typhoid is sure to light up a recurrence. With this in mind, when a case of typhoid fever presents among its earliest symptoms pain to the right of the hypogastric region, with tenderness, nausea or vomiting, aching or discomfort in the groin, anorexia, and lastly, rigidity of the right rectus, a relighting up of a previous disease should be suspected, for it is now known that the right iliac fossa is not tender during the early days of typhoid, before the bacilli have been deposited in the Peyer's patches. Immediate laparotomy should then be done, removing not only the appendix, but also the agglutinated coils of the ileum, which thus has its nutrition impaired and consequently its structural resistance is diminished.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JUNE 4, 1904.

"LEAD, KINDLY LIGHT."

BROOKLYN, which has hitherto been celebrated principally for its churches and its bridge connection with what it fondly regards as its suburbs, has now come out in a new rôle, and seems to have developed into a place where they "find out things." Their last discovery, and one which will be of greater service to their neighbors perhaps than to themselves, is the rather startling fact, that artificial teeth, made of porcelain, are a certain and reliable protection against sudden death, due to poisoning from the inhalation of illuminating gas.

Now, whatever may be charged to the account of the inhabitants of Brooklyn, they are certainly not, as a class, addicted to the playful and labor-saving habit of "blowing out the gas," and the guileless and unsophisticated stranger who has money to burn, is much more apt to consume it in feeding the flame of some red lamp on the altar of a New York dive, on a Saturday night, than he is to drop it with an unshaking hand into the contribution box of a Brooklyn church on Sunday morning. Actuated, it would seem, by a realization of this fact, and doubtless influenced by the belief that short credits make long friendships, the authorities of the gas companies of Brooklyn have evolved from their inner consciousness a system which, while it may bring peace to the treasurer, certainly passeth all understanding of other communities. For these gas magnates take no chances. With one fell swoop they have done away with bills and the difficulties of their collection, and have eliminated all meters from the equation of their business enterprises. In place of them they have set up an automatic fountain head, a thing of cogs and balances, that acts upon the introduction of a silver quarter of a dollar as does the more humble slot machine, when the insertion of a nickel throws down a bar of stored muscular energy in the shape of chewing gum, or, like Helen's babies, "makes the wheels go round."

These mechanical devices are not only useful, but are highly ornate, and are calculated to make any home, uninhabited by the color-blind, happy. For the directions "Drop a quarter in the slot and secure your gas supply," which are tastefully enameled in various chromatic schemes on their convex fronts, not only proclaim the touch of the modern impressionist, but are as direct, and as easily understood as the inscription painted by some wag on the lodge of the Indians in the vast wilderness of the Wild West Show: "Throw a brick into the tent and see the Indian come out." All this is easy and plain sailing for the company, and would be simple enough for the consumer, if each apartment had a separate and individual connection with the gas supply, but when the machine in one room turns on the gas in the rest, so that one man's meat becomes another man's poison, the complications are apt to be dangerous, to say the least.

The first victim to the grasping greed of this monopoly seems to have been a certain Dr. Westfall, who, returning late to his room in his boarding house, lighted a match, and applying it to the gas burner, suddenly realized that he was in personal contact with a corporation that did not propose to let its light shine before men without adequate and guaranteed compensation. A hurried search through his clothes and belongings failed to discover a coin of the proper denomination, and as there were some five flights of stairs between the doctor and the outer world, and as the patent machine had not been perfected to a degree that would enable it to make change, he quietly undressed, and going to bed in the dark, was soon asleep.

Up to this time, according to the evidence, Dr. Westfall's course of action had been marked by the good sense and calm deliberation that is es-

sential to a professional man, not only in Brooklyn, but in other places. He did not have a silver quarter; there was no possibility of obtaining one from the neighboring shops, which were, of course, closed at midnight, so that, like "Little Ned who was sent to bed," he also, in our judgment, "acted right." His one mistake, however, was that he did not turn back the key after his futile endeavor to light the gas. Shortly after this a fellow lodger in another part of the house came in, and finding that his lamps, too, were untrimmed when the bridegroom came, he dropped the requisite coin and the gas immediately began to flow. It flowed, however, not only into his own room, but also into that of Dr. Westfall, and with the usual result. But the sleeping man awoke. Something had gotten into his throat and was strangling him, and it was only with the greatest difficulty that he reached the window and throwing it open screamed for help.

And now this gentleman from Brooklyn comes into the arena of controversy with a brand new theory, that porcelain teeth are a perfect safeguard against asphyxiation, and that no well-established victim of the gas-blowing habit should be without them. For he tells us, "escaping gas causes the unconscious sufferers to grind their teeth and says that in grinding his china molar was broken and that the fragments falling into his throat, awakened him." All this may be and probably is true, but we doubt if what Bret Harte described in the address to the pliocene skull as "a thrill of the maxilla and a lateral movement of the condyloid process" would be always sufficient to dislodge the results of modern, up-to-date dental substitution, as in some cases tooth would be undeniably stronger than friction. At all events, an ounce of prevention is worth a pound of cure, and it would have been easier and far cheaper in the end for the doctor to have coughed up the price of the gas than the fragments of his tooth, which must have been sharper even than having the proverbial thankless child.

As to the dispute between Dr. Westfall and the gas company, our sympathies are, in this case, with the corporation. We do not know what particular specialty Dr. Westfall is following, so, far be it from us to suggest that he may be a dental surgeon who is seeking to advertise the virtues of porcelain teeth as a protection for persons who blow out the gas. But reciprocity is the soul of mutual compacts, and as he gave no quarter to the company, he can expect none in return from them, their machines or anything that is theirs.

THE PATENT MEDICINE CURSE.

We have watched with no little interest the amount of attention that has been aroused in many quarters by the article of Mr. Bok, the editor of the *Ladies' Home Journal,* with regard to the patent medicine curse, which appeared in the May number of that monthly. Something over a year ago there was copied, with due acknowledgments, in one of the departments of the *Ladies' Home Journal,* a passage from the Byways of Medical Literature of the Medical News, in which it was shown that most of the patent medicines used in this country contain considerably more alcohol than beer or even wine, and that many of them compare not unfavorably in alcoholic strength with the ordinary whisky that is sold in saloons. Not long since a personal communication from Mr. Bok asked us for further information with regard to this subject, which, so far as it was possible, we supplied, calling attention particularly to the analyses published some years ago by the Massachusetts Board of Health. We have felt then that it was rather the proper thing for us, in view of the sensation that has ensued, to see what others would say before taking part in the interesting discussion.

We are overjoyed to note that Mr. Bok has hit straight from the shoulder, that his attitude has attracted widespread attention, and has led to comment on the part of most of the self-respecting journals throughout the country. Of course it cannot be expected that newspapers which derive a considerable portion of their advertising income from display announcements of these patent medicines will give any space or notice to a movement that is likely to diminish the receipts of their advertising departments. An independent journal like *Collier's,* for instance, speaks out fearlessly and says: "Mr. Bok appears with an article of which any journalist might be proud, attacking an outrage with truth and potency. The people who drink or eat patent medicine number millions. Some do it to save doctor's bills, others because they find the patent medicine more effective, since no reputable doctor would give in quantity and kind what the patent medicine contains. The law which forbids harmless oleomargarine to be used as butter does not prevent poisons containing from 20 to 45 per cent. of alcohol from being sold as non-alcoholic." *Collier's* adds, "The Women's Christian Temperance Union busies itself with such important matters as christening ships with wine. Life insurance

companies, more intelligent, have begun to ask their applicants whether they have a habit of using patent medicines." These preparations are popular in prohibition States.

As Mr. Bok very truthfully points out in his article in the *Ladies' Home Journal,* it is to a large extent the religious journals throughout the country that have been most flagrant in their readiness to accept patent medicine advertisements. He says, "Beside me, as I write, are issues of some twenty different religious weeklies, the advertising columns of which are a positive stench in the nostrils of self-respecting people." There is no doubt of the truth of this. Medical journals have called attention over and over again to the discrepancies between the lofty declarations of the editorial and other columns of the religious press, and the utter sordidness of the advertising columns. Almost anyone who has the money and who does not make an open profession of immorality, can get into the advertising columns, even of the highest class religious periodicals. This field has been considered one of the most lucrative by medical advisers generally.

We note that another phase of the medical advertising evil has also been brought before the public just at this time. A number of sketches of Mr. Hearst, one of the presidential possibilities, have recently appeared, and in answer to one of them Mr. Norman Hapgood wrote a typical editorial as it should appear in the Hearst papers, but will not. He says:

"To the billion readers in our Hearst family,—one word. Let them examine this paper. They will find over a page of advertisements by quack doctors, of a kind which reputable papers will not print. They will find masses of advertisements on patent medicines. One contains 44 per cent. of alcohol. One, advertised as 'safe,' contains over 35 per cent. We know they are poison. We aid and abet clairvoyants, palmists, astrologers and card-readers. Why do we carry all these schemes to cheat the poor? Did you ever study proportion? Neither has the poor savage of Australia; but we have, and our morality is determined by the ratio of cost to what we get out of it. As it is in these petty swindles, so is it in the larger bunco games of politics. We defend the poor when it pays. We cheat the poor when it pays. Think it over."

Both of these excellent hits at the evils of medical advertising have appeared in *Collier's,* and yet *Collier's* itself lends its columns for due remuneration (we wonder if, as is said to be the case with the religious press, the price for medical "ads" is higher than for any other advertising material) to medical advertisers who are likely to do just as much harm as ever did the alcoholic patent medicines. Every honest man now knows that medical advertising in the lay press is only for the purpose of exploiting poor sufferers whose ailments make them even less capable of proper judgment than before. The only position for a self-respecting managing editor to take is absolutely to refuse all such advertisements, no matter what the stipend offered for them. This Mr. Bok did some time ago with regard to the *Ladies' Home Journal,* and, as the result, has had the courage to take the next step of directly attacking the evil. If this example will be followed by other prominent journals there will be a distinct raising of the moral tone in editorial rooms generally throughout the country. Let us hope that the evolution is about to come. The medical profession should be ready to encourage it in every way and should note the papers that are striving to be honest in the midst of so much disgraceful sordidness.

SOCIETY OF SANITARY AND MORAL PROPHYLAXIS.

WHAT promises to be a most important movement in diminishing the spread of venereal diseases in this country—viz., the organization of a society of sanitary and moral prophylaxis—seems to be on the eve of successful accomplishment. This project has received the unanimous endorsement of the New York County Medical Society and the active cooperation of many influential members of the laity has been promised.

As set forth in the paper of Dr. Morrow, in the present issue of the MEDICAL NEWS, the prophylaxis of venereal diseases, from their peculiar nature and mode of propagation, is not purely a sanitary problem; it is essentially a sociological problem. To combat the evil there is required a union of all the social forces—medical, moral and legislative.

Any attempt to introduce the Continental system of regulation in this country has always encountered a strong hostility on the part of the moral element of society—but there can be no opposition to a movement which is chiefly along the lines of education of the rising generation in matters relative to the physiology and hygiene of the reproductive organs.

Readers of the MEDICAL NEWS may recall our full reports of the two International Congresses

for Sanitary and Moral Prophylaxis, held at Brussels within the past five years. The organizations which have evolved from these meetings have had a very marked success in European countries; the German society now numbering over four thousand members and the French society almost a thousand. Swiss, English, Dutch, Italian, and Russian branches are operative.

It is fitting that an American organization, in sympathy with the European movement and representative of the best elements not only in the medical profession but of the law, the clergy, and the layman should be launched at this time.

We can confidently hope for a permanent organization in the very near future.

REPORT OF THE ENGLISH CANCER RESEARCH FUND.

It has always been a characteristic of English science, and, indeed, of English thought in every field of human interest, that its greatest advances and its most noted triumphs have come not from the schools or the institutes, but from individuals working alone and independently. Herbert Spencer, Charles Darwin, Mill, Buckle, and innumerable other names attest the truth of an observation which is by no means new, yet always remarkable. In France, the Academy and the University of Paris have been the springs and sources of all progress; in Germany, it is hard to discover a famous name unadorned by the title of Professor or Director.

The establishment, therefore, of a special fund, of an institution, under the patronage of His Majesty the King and under the presidency of H.R.H. the Prince of Wales, for the investigation of the causes and nature of cancer, is an experiment which will be watched with much interest. It is of significance inasmuch as it takes official cognizance of the tremendous growth and the really serious national import of the disease. It is still further of significance inasmuch as it postulates that the problem is too vast to be entrusted to individual effort. These two considerations give abundant sanction to the establishment of the Foundation.

The first scientific report of the investigations of the Cancer Research Fund has just been published, and contains a résumé by Dr. E. F. Bashford of recent work in the laboratory. In consonance with the essential idea of the Fund, the work has been undertaken along extremely broad and extensive lines of research, comprising the zoological distribution, the transmissibility, and the comparative histological and cytological characters of malignant new growths. These are all large and fundamental problems, which necessitate the accumulation of a vast amount of material, of data, and of labor, and are eminently within the domain of such an institution, as contrasted with the problems accessible to the individual investigator. As might have been anticipated, the early results are suggestive, promising—but nothing more; indeed, to expect more would be entirely to underestimate, and mistake the nature of the issues.

It appears now to be a matter beyond dispute, that tumor formation is a condition which maintains not only among men, but among all forms of domesticated animals, and, as well, among wild vertebrates from the fish up. The only general factor which seems to influence its origin is the mature age of the victim. The tumors, as in man, derive their nature from the character of the parent tissue-cells, and are broadly divisible into the epiblastic and mesoblastic types. These data are of importance as revealing the action of some generalized etiological factor. It is evident that the immediate problem is to determine whether this be of a parasitic nature or not. Experiments in the transmissibility of tumor, therefore, form one of the most interesting and vital aspects of the work. It has long been known, from the investigations of Jensen and others, that malignant new growths are inoculable under certain circumstances from one animal to others of the same species. The conditions governing the success of these inoculations, however, seem to indicate almost conclusively that the transmission is one not of a parasite, but of the cellular growth itself.

Thus, in the last instance, the problem resolves itself into one of cellular biology, and it is apparently upon this standpoint that it must be attacked.

What are the factors which dissolve the laws of cellular interdependence within the organism, and endow a certain group of these elements with a faculty of vicious and unlimited proliferation, making of them, as it were, another unit within the greater unit? Two histological features of neoplastic growths have been pointed out, as affording a possible explanation of this metamorphosis in the character of the cells. First, there is the conjugation of nuclei which has been observed between cells of these growths; second,

there are the phenomena of so-called "gametoid" karyokinesis, in other words, a type of cellular mitosis which imitates that characteristic of the germinal cells (spermatic and ovarian) and differs markedly from that of the somatic cells. Conjugation, it is suggested, may act as a stimulus to cellular growth and proliferation, as in the protozoa. Reversal of the type of cellular division may be the cause of a reproductive capacity similar to that of the germ cells themselves.

These suggestions are very plausible, very interesting, and, indeed, quite attractive. It is wise, however, to temper one's acceptance, even if only provisional, with something of critical coolness. Granted that the phenomena are correctly interpreted as observed, it is somewhat rash to attribute to them an etiological significance. The processes of cellular division in new growths are notoriously so irregular and so heterogeneous, so rich in novel and abnormal conditions, that it appears unjustifiable arbitration to select one type as the *causa morbi*. It is certainly as logical to regard these particular variations as a phenomenon, a symptom, of the altered cellular activity, rather than as a cause. But even if they be so considered, it still remains to be shown that conjugation or reversion to the gametoid type are efficient causes in the metazoa of malignant proliferation. Certainly, there is as yet not a scintilla of evidence to prove this.

The difficulty of the problem is apparently commensurate with its importance. The Cancer Research Fund has not solved it, although its efforts appear to be directed along the most promising path. It is to be hoped that every advantage and opportunity will be offered for the prosecution of the investigation. Meanwhile, patience, reserve and serious criticism are the part and the privilege of those who eagerly look for some light in the darkness that envelops us.

ECHOES AND NEWS.

NEW YORK.

Appointment of Dr. Opitz.—Dr. Burton-Opitz has been promoted to the Adjunct Professorship in Physiology at Columbia University (P. & S.), with a seat in the faculty of pure science.

Resignation of Dr. Lefferts.—At a meeting of the Faculty of Medicine of Columbia University, held May 23, 1904, it was voted that the following minute be entered on the records of the meeting and that a copy thereof be sent to Dr. Lefferts: "Upon the acceptance of the resignation of George Morewood Lefferts, M.D., M.Sc., Clinical Professor of Laryngology and Rhinology at the College of Physicians and Surgeons, the Medical Department of Columbia University in the City of New York, the Faculty of the College desires to express its high appreciation of the distinguished services which through three decades he has rendered to the institution. The organization and maintenance of an important practical clinical department in the College, eagerly sought by the students of successive generations, and a model of efficient administration, we recognize as a large achievement in the career of a busy practitioner. This long and faithful service and the generous gift to the College of a valuable collection of illustrative specimens and charts are held in high appreciation by his colleagues. A wise and successful teacher, an eminent practitioner, and a genial associate, the Faculty acquiesces in Dr. Lefferts' retirement with reluctance and regret."

Another Sneak Thief.—Several physicians in Harlem are anxious to get their hands on a gentlemanly sneak thief who has been helping himself to the contents of their households. The latest to suffer is Dr. A. J. Bilhoefer of 79 East 116th street, who was robbed of $3,000 a few days ago. The thief called at the doctor's residence in his absence and said he wanted to see Dr. Bilhoefer on very important business. He said he would wait until the doctor came in. Mrs. Bilhoefer was in the basement and the servant went about her duties, leaving the man in the parlor. He then went through the upper floors and took all the jewelry he could find. The same thief is supposed to have paid a visit to the residence of Dr. I. L. Feinberg at 1716 Madison avenue and worked the same game. He did not make out quite so well, as valuables easily carried off were locked up. A number of physicians on the west side of Harlem have been caught by the same thief.

A Mosquito Year.—"Evidence is accumulating," says the *Times*, "that this is going to be a great mosquito year. It is reported that fishermen and surveyors have been obliged to abandon the oyster reefs of Louisiana because of the unprecedented numbers of these fever-infected insects. From New Jersey and other regions come complaints indicating that the mosquitoes are going to break the record. But while in some places concerted efforts are being made to exterminate, or at least mitigate, this plague, Manhattan is given over as a prey to the deadliest of all animals without a struggle. Central Park presents conditions which the most ingenious planning could hardly make more favorable for the breeding of mosquitoes. The ponds are in a deplorably neglected and shamefully filthy condition. A foul-smelling green scum covers the shallow, stagnant water; yesterday old newspapers and tin cans were floating on one of them. The benches placed near these ponds are occupied every afternoon mostly by nurse maids in charge of infants. Mosquitoes abound, and the doctors are tracing cases of malaria to their bites. On windless nights the mosquitoes rise and molest families living in the highest stories of the buildings along Central Park West. It is getting to be risky even to walk through the park. And all this simply because the authorities in charge have not seen fit to resort to the well-known, inexpensive means of combating this evil. The simplest way to abate it would be to keep the water in the ponds clean enough for fish to live in them; they eat the larvæ of the insects. It is only since the fish found life impossible in the polluted water that mosquitoes have become abundant up town."

Pneumonia and Tuberculosis in Chicago and New York.—The term of pneumonia is nearly over for the present season. Since Nov. 1, 1903, there have been 3,703 deaths in Chicago from this cause out of a total of 16,780 deaths from all causes—a proportion of more than one-fifth (22.06 per cent.) of the total mortality. From consumption during the same period there have

been 1,806 deaths, or less than one-half those from pneumonia. Tabulated the deaths from these two causes of death for Chicago and New York between Nov. 1, 1903, and May 28, 1904:

	New York.	Chicago.
Total deaths, all causes	46,999	16,780
Deaths from consumption	5,228	1,806
Deaths from pneumonia	9,865	3,703
Proportion per cent. of all deaths—		
From consumption	11.12	10.76
From pneumonia	20.98	22.06

PHILADELPHIA.

Medico-Chirurgical Commencement.—At the annual commencement of the Medico-Chirurgical College held on May 28, diplomas were awarded to 127 graduates. Of these, 70 were in medicine, 36 in pharmacy and 21 in dentistry. The address to the graduates was delivered by President Swain of Swarthmore College.

Medical Class Organizes.—The class of 1894 of Jefferson Medical College held its first reunion in this city May 27, and effected a permanent organization. The following officers were chosen: President, Dr. W. H. King; Vice-President, Dr. R. C. Rosenberger; Secretary-Treasurer, Dr. W. A. Brinton. A reunion will be held every five years.

Blood Poisoning an Accident.—Judge Buffington, in the United States Circuit Court, has refused a new trial in the case of Katherine Nax against the Travelers Insurance Company, in which she recovered judgment on a $5,000 accident insurance policy held by her husband. In 1902 Mr. Nax died from blood poisoning that resulted from paring a corn too deeply. The company refused to pay the policy on the ground that death was not due to an accident. A jury decided in favor of the widow and Judge Buffington, in refusing a new trial, said that death under such circumstances is as much an accident as if the victim had died as the result of any other unforeseen catastrophe.

Chemical Disinfection of Water.—In reply to the suggestion of the Trades League that electrozone be used for purifying the water supply of the city, Director Martin has virtually stated that chemical disinfection of water is, at present at least, impracticable. A report by Dr. Abbott shows that the electrozone plant at full capacity could furnish only one-twentieth the amount required for the smallest reservoir. In addition, it leaves a slight taste of chlorine as do any of the chloride compounds. Another method under trial will be reported upon later.

Meeting of Associated Health Authorities.—The eleventh annual meeting of the Associated Health Authorities and Sanitarians of Pennsylvania was held at Gettysburg, May 27 and 28. Two important topics considered were the registration of vital statistics and the securing of improved sanitary measures for the State. Dr. Cressy L. Wilbur, of the United States Census Bureau, delivered the annual address on the former topic. A committee was appointed to draft a bill providing for the appointment by the State Board of Officers and Deputy Officers of Health in each county; these are to be under the supervision of the State Board. This would carry with it the repeal of the act of 1889 which provided that school boards may organize as health boards. The working of this law has never been satisfactory. The following officers were unanimously elected: First Vice-President, Dr. S. P. Heilman, of Heilmandale; Second Vice-President, Dr. T. N. McKee, of Kittanning; Third Vice-President, Dr. R. S. Maison, of Chester; Treasurer, Dr. Jesse C. Green, of West Chester; Secretary, Dr. Wilbur R. Batt, of Philadelphia. The Governor of the State is *ex-officio* president.

CHICAGO.

Chicago Policlinic.—Plans have been decided on for the erection of a $150,000 building for the Chicago Policlinic and Hospital at Oak Street and La Salle Avenue. The hospital will be equipped for one hundred patients. At present it is situated at Chicago Avenue, where it has been for eighteen years. The new hospital will be the only institution of its kind owned by physicians and not conducted for profit. Bonds for $150,000 will be issued and work will be begun as soon as possible. Dr. Fernand Henrotin is President; Dr. R. D. MacArthur, Vice-President; Dr. John H. Chew, Treasurer, and Dr. M. L. Harris, Secretary.

University of Illinois Commencement Exercises.—A class of 219 was graduated from the College of Physicians and Surgeons, the Medical Department of the University of Illinois, May 24. Prof. Thomas J. Burrill, Vice-President of the University, conferred the degrees, and Rev. A. R. Lambert delivered the doctorate address.

Illness of Dr. Newman.—Dr. Henry P. Newman, Treasurer of the American Medical Association, was operated on for appendicitis May 21, and the appendix removed. It is said that he bore the operation well, and is progressing favorably toward recovery.

Reciprocity Convention.—The third annual convention of the American Confederation of Reciprocating, Examining and Licensing Medical Boards was held in Chicago, May 24. The Examining or Licensing Boards of the States of Illinois, Indiana, Wisconsin, Michigan, Iowa, Nebraska, Kentucky and Maryland were represented. The address of the President, Dr. W. A. Spurgeon, Muncie, Ind., dwelt on the insufficiency of the courses in the colleges and the lack of proper relation between the various branches. He advocated regulation of the medical college curricula, and of State Board questions as a basis for reciprocity and uniformity.

A Chief Predisposing Cause of Appendicitis; Preliminary Note, with a Few Laboratory Experiments.—Dr. George Rubin, after reporting a case of this disease, detailed some experimental work. The technic was as follows: Portions of bowel, about 50 cm. long, including cecum and appendix, were resected from subjects dead of other diseases than what would affect that part of the intestinal tract. Specimens from very recent post mortems were more desirable, but were not always obtainable. After cleansing the piece of bowel, the colon end was ligated; shot, peas and beans were introduced through the ileum end and the bowel manipulated so as to indicate more or less peristalsis. The rolling of those bodies was often done with more vigor than normal peristalsis would do. It was observed that none of the contents entered the cavity, although the appendix was held at the most dependent point. Then the bowel was inflated, still containing those substances, the same process of rolling again gone through, with the result that in all the experiments, with one exception, where only one small shot entered, owing to a highly hypertrophied appendix wall and constricted lumen, the appendiceal cavity was filled with shot and in two cases peas of medium size gained entrance there. Ten such experiments were carried out. The appendix was readily ballooned during the process of inflation. It is reasonable to suppose, said the author, that similar phenomena might occur in the living. Fitz recorded 19 out of 267 cases of appendicitis which were supposed to be due to indirect violence. Such cases can only be explained in the following manner, that by forcing a larger mass of fecal matter through the ceco-appendicular orifice than the appendix is able to expel, following that trauma to the mucosa with subsequent infection taking

place. It is not improbable that heavy labor, such as heavy lifting, may operate in a similar manner, *i.e.*, owing to the increased intra-abdominal pressure produced by tension of the abdominal wall. These considerations help to explain the marked disproportion in the sexes. Regarding the size of the obstructing mass, no definite statement can be made. The calibers of appendices vary very much. What would be an insignificant particle for one may completely obstruct another. As to the rôle the valve of Gerlach plays in preventing matter from entering the appendix, little can be said, as in all the specimens of bowel the author has examined, in only one was there a lengthening of the mucosa that might have been called a valve. Under ordinary circumstances, the mucous lining itself is sufficient to act as such.

CANADA.

Personals.—Dr. C. R. Elliott, formerly resident physician at St. Michael's and the General Hospitals, Toronto, has been appointed by the United States Government surgeon at the marine hospital, Seattle.

Dr. J. W. Harris, resident physician at the Toronto General Hospital, has been appointed to the position of relieving physician to the Insane Asylums of Ontario.

Dr. C. E. Dougherty, the assistant medical superintendent of the hospital for the insane at New Westminster, B. C., has resigned and will become superintendent of the hospital at the mining camp of Ymir.

News from Queen's, Kingston, Ont.—At a meeting of the medical faculty of Queen's held on the 25th of May, it was decided that the matriculation standard of the Ontario Medical Council was high enough at present. A leading lawyer of Kingston will be appointed to give a series of lectures next session in connection with the subject of medical jurisprudence.

Dr. J. C. Connell, Dean of the Medical Faculty of Queen's University, has received word that Cambridge University would grant recognition to Queen's medical course. This means that Queen's medical students, after spending a session or two or three at Kingston, will have the privilege if they desire of going to Cambridge and completing their course there, full allowance being given for their attendance at Queen's.

New Appointments in the Faculty of Medicine at McGill.—At the last meeting of the Board of Governors of McGill University the following appointments were made in the Medical Faculty: Dr. R. Tait McKenzie to be lecturer in anatomy; Dr. A. A. Robertson to be lecturer in physiology; Dr. W. G. M. Rogers to be lecturer in ophthalmology; Dr. J. W. Scane to be lecturer in pharmacology and therapeutics; Dr. W. S. Morrow to be associate professor of physiology; Dr. A. G. Nichols to be associate professor of pathology and bacteriology.

Consumption Sanitaria in Canada.—At a meeting of the executive council of the Canadian Association for the Prevention of Tuberculosis, a committee consisting of Dr. P. H. Bryce, convener; Dr. J. D. Lafferty, Calgary, N. W. T.; Dr. C. J. Fagan, Victoria, B. C.; Dr. Gordon Bell, Winnipeg, and several laymen was appointed to take steps to secure the cooperation of municipalities and of the governments of the several provinces and of the Government of the Dominion of Canada for the establishment of one large sanitarium in each province for the treatment of consumption. The secretary of the Association was instructed to visit Prince Edward Island, Nova Scotia and New Brunswick in August and September with a view to lecture upon the cause and prevention of consumption and to lecture in Ontario during June and July; and in addition a special committee was appointed of all members of the Association resident in Ottawa with Dr. H. B. Small as convener to take steps to organize for the work in that city.

Nova Scotia's Consumption Sanitarium Opened.—The Province of Nova Scotia, by an Act passed March 30, 1900, appropriated a sum of money for the erection of a consumption sanitarium for tuberculous disease of the lungs. The institution has been declared formally opened, but will not receive patients until the first of July. This government sanitarium is situated about three-quarters of a mile from the town of Kentville, about seventy miles from Halifax. The building cost without furnishings $20,000, and has accommodations for 20 patients. The Act provides that there shall be appointed two examining physicians and that both shall be residents of Halifax, but these have not as yet been selected. There will be no resident physician, but arrangements will be made whereby one of the physicians of Kentville will make frequent visits to the institution. In the meantime the institution will be under the charge of the lady superintendent who is a graduate of one of the Boston hospitals, and who has had special training in the Massachusetts State Sanitarium and in the Sharon Institution.

GENERAL.

Medical Interne.—Government Hospital for the Insane. The United States Civil Service Commission announces an examination on June 29-30, 1904, to secure eligibles from which to make certification to fill at least two vacancies in the position of medical interne in the Government Hospital for the Insane, Washington, D. C., at $600 per annum each, and other similar vacancies as they may occur in that hospital. The examination will consist of the subjects mentioned below, valued as indicated:

Subjects.	*Weights.*
1. Letter-writing (the subject-matter on a topic relative to the practice of medicine)	5
2. Anatomy and physiology (general questions on anatomy and physiology, and histologic or minute anatomy)	15
3. Chemistry, materia medica, and therapeutics (elementary questions in inorganic and organic chemistry; the physiological action and therapeutic uses and doses of drugs)	10
4. Surgery and surgical pathology (general surgery, surgical diagnosis; the pathology of surgical diseases)	20
5. General pathology and practice (the symptomatology, etiology, diagnosis, pathology, and treatment of disease)	25
6. Bacteriology and hygiene (bacteriologic methods, especially those relating to diagnosis; the application of hygienic methods in prophylaxis and treatment)	10
7. Obstetrics and gynecology (the general practice of obstetrics; diseases of women, their pathology, diagnosis, symptoms, and treatment, medical and surgical)	15
Total	100

Age limit, twenty years or over. This examination is open to all citizens of the United States who comply with the requirements. Applicants must be graduates of reputable medical colleges. Applicants should at once apply either to the United States Civil Service Commission, Washington, D. C., or to the secretary of the local board of examiners at the places mentioned in application Form 1312. No application will be accepted unless properly executed and filed with the Commission at Washington prior to the hour of closing business on June 22, 1904. In

applying for this examination the exact title as given at the head of this announcement should be used in the application.

Rush Monument Dedication.—The Rush Monument Committee of the American Medical Association will unveil and dedicate the monument to Benjamin Rush, on Saturday, June 11, 1904, at 5 o'clock P.M., on the grounds of the Naval Museum of Hygiene and Medical School, Twenty-third and E streets, N. W., Washington, D. C. An introductory address by the president of the American Medical Association will be made and a eulogy of Rush by Dr. J. C. Wilson, of Philadelphia, delivered. An acceptance of the monument as a gift to the nation will be made by the President of the United States.

International Tuberculosis Congress.—The International Tuberculosis Congress was formally opened in Parliament House, Copenhagen, last Friday, under the presidency of Professor Brouardel, of Paris. Crown Prince Frederik, the Ministers and members of the Diplomatic Corps, including the United States Minister, Mr. Swenson, were among those in attendance. Delegates from twenty countries, among them Dr. Pottenger, of Los Angeles, Cal., and E. L. Trudeau, of New York, were present. The Premier, M. Deuntzer, welcomed the delegates.

The American Gynecological Society will meet next year at Niagara Falls. The officers elected for the ensuing year are: President, E. C. Dudley, Chicago; vice-presidents, H. D. Fry, Washington, and H. C. Coe, New York; treasurer, J. M. Baldy, Philadelphia; secretary, J. Riddle Goffe, New York. The society amended its constitution to read as follows: "The object of this Society shall be the promotion of knowledge in all that relates to diseases of women, to obstetrics and *to abdominal surgery.*"

Walter Reed Memorial Association.—The Walter Reed Memorial Association has been incorporated under the General Laws of the District of Columbia, to give unity to the various proposals which have been made for the securing of a Memorial Fund. This Association is now organized for the collection and care of such sums as may be entrusted to it. Printed papers explanatory of the services of Major Reed, U.S.A., and respecting this Association are ready for distribution and will be sent to those who apply for them. Contributions from individuals, medical societies, boards of trade and other business organizations are now solicited. They may be sent to the treasurer, Charles J. Bell, American Security and Trust Company, Washington, D. C., by whom they will be acknowledged.

Kalamazoo Hospital.—On May 24 the corner-stone of the new Kalamazoo Hospital at Kalamazoo, Mich., was laid with appropriate ceremonies that were participated in by many of the prominent citizens of the town. Addresses were made by the Mayor, James W. Osborn, Rev. E. J. Blekkink, Dr. H. B. Osborne, Rev. W. M. Puffer, D.D., and Rev. H. W. Gelston, D.D. Music was rendered by a quartet, and at the close of the exercises the entire audience united in singing "America." The Kalamazoo Hospital is the result of four years hard work, and the laying of the corner-stone marks the reality of this much-needed addition to the beneficent institutions of the town. The money for the building has been raised by unceasing efforts of the women of the city, who united in one grand endeavor to secure this city hospital. Hundreds of contributions have been made, bazars, trolley-days, what-so-ever circles, and entertainments of other kinds have combined with the liberality of a few leading citizens in producing the required sum of money. The building is to cost $28,000, exclusive of the plumbing and heating, and the money has all been raised. The principal gifts were from Dr. Edwin H. Van Deusen, $10,000; the estate of Horace B. Peck, $5,000; the Woman's Auxiliary, $8,025, and the remainder has been contributed by smaller subscriptions. When completed the hospital will have 40 beds. It is nonsectarian, open to all the citizens of the town as well as strangers, and with its sister institution, the Borgess Hospital, will furnish room for the care of all the sick and emergency cases of the city for a considerable time to come. The present officers of the association are Dr. W. E. Upjohn, President; Mrs. C. H. Williams, Vice-President; E. J. Phelps, Treasurer; Guy Van de Kreeke, Secretary.

Phi Chi Fraternity.—At the National Convention of the Phi Chi Fraternity (medical), held in Burlington, Vt., May 25, 1904, Dr. F. E. Clarke, Instructor of Histology and Pathology in the Medical Department of the University of Vermont, was elected Grand President. That evening the local, Alpha Chapter, gave a banquet to the visiting delegates and the members of the faculty at the Van Ness House; President Clarke acting as toastmaster. Among those present who responded to toasts were: Dr. A. O. J. Kelley, of Philadelphia, Pa.; Dr. A. R. Shands, of Washington, D. C.; Dr. H. C. Tinckham, Demonstrator of the Faculty of the Medical Department of the University of Vermont, and President Matthew Henry Buckham, of the University. The next national convention will be held in Baltimore, Md., some time in January, 1905.

Consumption from Cattle.—The royal commission, appointed in August, 1901, to investigate the connection between human and animal tuberculosis, has reached certain conclusions embodied in an *ad interim* report, which in effect refutes Prof. Koch's much discussed theory that tuberculosis cannot be communicated by animals to human beings. The commissioners attacked the problem experimentally instead of beginning by collecting opinions, and their main conclusion is thus expressed: "We have most carefully compared the tuberculosis set up in bovine animals by materials of human origin with that set up in bovine animals by material of bovine origin, and so far have found the one, both in its broad general features and in its finer histological details, identical with the other. Our records contain accounts of post-mortem examinations of bovine animals infected with the tuberculosis material of human beings which might be used as typical descriptions of ordinary bovine tuberculosis." This, in the judgment of the commissioners, "seems to show quite clearly that it would be very unwise to frame or modify legislative measures in accordance with the view that human and bovine tubercle bacilli are specifically different and that the disease caused by one is wholly different from the disease caused by the other." The commissioners experimented with more than two hundred bovine animals. Their present conclusions, which will be followed by a further report, strikingly support the view of a majority of English medical men and are likely to lead to a strengthening of the regulations regarding the sale of meat and milk.

OBITUARY.

Dr. Ralph N. Isham, for nearly half a century one of the leading physicians of Chicago, died last week at the home of his daughter, at Lake Forest, Ill.

Dr. Thomas Murray Drysdale, the well-known gynecologist, is dead at the age of seventy-three years. He was born and educated in Philadelphia and practised there except during the time he was in the Civil War.

Dr. Drysdale held various teaching and honorary positions and was prominent in his specialty.

Dr. F. SAVARY PEARCE, Professor of Neurology at the Medico-Chirurgical College, Philadelphia, died at the home of his father in Steubenville, Ohio, May 27, at the age of thirty-seven years. Excessive application to work, especially in the preparation of text-books, led to a breakdown that ultimately resulted in death. Dr. Pearce graduated from the University of Pennsylvania in 1891 and had been connected with the Medico-Chirurgical College for four years.

SPECIAL ARTICLE.

BYWAYS OF MEDICAL LITERATURE.—XXI.

PROTOZOA AND DISEASE.

IN the April number of the *Century Magazine*, Dr. Gary Calkins, Adjunct Professor of Zoology at Columbia University, has an excellent article on the etiological connection between certain forms of protozoa and infectious diseases in human beings, that while popularly interesting is thoroughly scientific. At the present time it must be recalled that some of the most important diseases that afflict mankind, among them some whose cause has longest remained a mystery, are either known to be due to protozoa, or, at least, the causes of these diseases are suspected to be of protozoan character. Malaria is surely due to a protozoon, or perhaps to several forms of protozoa, whose life history has now been worked out. Discoveries made last winter by Dr. F. B. Mallory, of Boston, seem to point surely to the fact that scarlet fever is also due to a protozoon. It is more than suspected now that yellow fever is due to the same form of parasite, and the analogy with malaria, because of the mosquito distribution, confirms this very strongly. It is easily seen then how important these microorganisms are. Two paragraphs from the beginning of Prof. Calkins' article give a very good idea of the place in nature of the protozoa:

"Since Pasteur demonstrated the fact that many human diseases are due to minute living things which grow and multiply in our bodies, there has been a tendency to call all microscopic organisms, whether harmful or not, 'germs' or 'microbes' or 'bacteria' indiscriminately. This confusion may be cleared by the statement that protozoa are the lowest known forms of animals and that bacteria are the lowest known forms of plants, while 'germs' and 'microbes' may apply to the disease-causing forms in either group.

"Protozoa are higher in the scale of living things than bacteria, their structures are far more complicated and their methods of living more complex, while most of them far surpass the bacteria in size, some, indeed, being visible to the naked eye. Like most bacteria, the majority of protozoa are absolutely harmless; but, unlike others (those that aid us in the digesting of our food, for example), no protozoa do us good except in the very general way of helping to maintain what is known as the 'balance of nature.'"

With regard to the etiological connection between protozoa and human diseases the first step was, of course, Laveran's discovery of the malarial organism. The connection of protozoa with smallpox has been suspected for at least as long a period as that, but the first step of demonstration was made in Italy. To quote Prof. Gary once more:

"As early as 1892 an Italian, Guarnieri, discovered a protozoon in vaccinated skin and the same protozoon in skin from smallpox patients. Guarnieri named the organism *Cytoryctes variolæ* and described it as the cause of smallpox. Neither he nor subsequent observers went further than this, and, until Dr. Councilman discovered them last spring, the most important stages in the life of the germ were overlooked. The stages of reproduction to which the virulence of smallpox must be attributed were made known by this discovery, and Councilman was able to give the very important generalization that vaccinia, or the mild disorder caused by vaccination, is due to the presence of the organism in the cell bodies of the human skin, while the more virulent disease, smallpox, is due to the presence of the same organism in the nuclei of these cells as well as in the cell-bodies."

While Prof. Calkins' illustrations give an excellent idea of certain stages of the protozoa which resemble the smallpox germ very closely he confesses that:

"It is not possible to describe the smallpox germ so as to convey an intelligible idea of its appearance. It has no definite form, but, like the free-living organism *Amœba proteus*, it constantly changes in shape. The reproductive bodies in the non-sexual phase are minute solid spheres, hardly visible when not in groups. The spores, which probably convey the disease from person to person, are equally minute, but differ from the former bodies by the presence of vesicles which occupy the greater part of the spores. This vesicle is characteristic of the entire group of *Microsporidia* in which *Cytoryctes* belongs, and it is probably an important element of the spore, for it reduces weight and renders it light enough to be wafted about by the lightest breath.

"Our knowledge of the smallpox organism is as yet very incomplete, and further experiments and study must be undertaken before it will be as clearly understood as are the organisms of malaria. The method of transmitting the disease from man to man, and the location of the parasite when outside of man, are quite unknown, but we are fortunate in the knowledge that the disease can be prevented by vaccination, the organism being injected into the skin-cells, where it undergoes a limited development and never grows into the destructive phase whereby the cells and nuclei of the skin are wrecked. The secret of this limitation is unknown, and it, together with the general problem of the immunity conferred by vaccination, remains for the future to solve.

"The discoveries of the protozoan parasites of malaria, smallpox, scarlet fever, and yellow fever should stimulate pathologists and biologists to a renewed study of other diseases in which the specific causes are unknown. Such study must lead to the further relief of human suffering, for as vaccination produces some slight change which makes the system unsuitable for growth of the smallpox organism, or as warfare on the mosquito limits the spread of yellow fever and malaria, so preventive or remedial measures will follow future observations and discoveries, and it is not too Utopian to believe that, before long, some comparatively simple means may be found to prevent or to cure diseases like scarlet fever or even cancer."

THE ATOMIC THEORY OF MATTER AGAIN.

Physicians generally are sufficiently interested in chemistry and chemical theory to have kept themselves to a considerable extent, at least, familiar with recent progress, real or supposed, as to the chemical and physical explanations of the constitution of matter. So much of the ordinary scientific journal has in very recent years been taken up with discussion of the ionic theory of the constitution of matter, that is, the theory which postulates ions (atoms) charged with certain dynamic principles, probably electrical in character, as the basis of matter, that the impression is apt to have

been produced that the old atomic theory of the constitution of matter had gone out entirely. This, however, is far from being true, and some recent publications, especially from the pen of Mendelejev, show that the atomic theory may still prove quite as vital as the newer ionic theory.

Mendelejev will be remembered as the distinguished Russian chemist who first showed the law of periodicity in atomic weight. About a quarter of a century ago or more this law proved very illuminating for chemistry and even pointed out the probable existence of certain elements as yet undiscovered which later were actually discovered. Mendelejev's law, as the application of his principle of periodicity came to be called, also proved very valuable as regards the relationship between the various elements and their action and reaction upon one another. It was even thought at one time that this law might be of use in the explanation of the physiological action of elementary substances, at least upon the body, and that its application might prove the basis for a system of rational therapeutics, as opposed to our present system of empiric therapeutics. Unfortunately this hope was never realized. Drug action upon the human or animal body is entirely too complex a matter to be explained by any mere chemical principle.

In a recent issue of *Prometheus*, a well-known continental journal of chemical science, Mendelejev has given a chemical explanation of the ether, and in doing so has also attempted to explain the radio-activity. As it is principally the phenomena of radio-activity which have proved most difficult of explanation on the old atomic theory, his words are of great interest. Besides, the ether itself as a substance which, according to the theory of the wave transmission of light, must be more elastic than steel, and yet is so tenuous as to penetrate all other substances, has had for many minds a mysterious aspect that made them think of it as something rather demanded as a part of a working hypothesis than as an actually existent material. It is not as such that Mendelejev treats it. We quote his expressions as they are given in *Science*, Vol. 19, No. 479, 1904:

"It cannot consist of matter known, disseminated in an exceedingly attenuated condition, because it penetrates all matter, nor can it be the 'Urstoff' (primal matter, original material) since this would involve the possibility of the annihilation and evolution of atoms. It must rather be considered as a definite chemical substance so light that its molecular velocity is great enough to overcome gravitation; it is without chemical affinity; its power of diffusion is so great that it can penetrate all bodies, and hence cannot be weighed, although it actually possesses an extremely small weight. Mendelejev would thus consider the ether to be the first member of the argon group in the periodic system, or what he calls the zero group, and places immediately before the alkali group. By extrapolation he posits an element in this group immediately before hydrogen, with an atomic weight of about 0.4. This he considers possibly identical with coronium. The ether must have a still smaller atomic weight, whose value, owing to this double extrapolation, is extremely doubtful, but certainly cannot be over 0.17. For this ether as an element he proposes the name of *Newtonium*. That the ether molecule can escape the attraction of the larger bodies of the universe its velocity must be, according to the kinetic theory of gases, at least 2,240 kilometers per second, and from this its atomic weight would be about one millionth that of hydrogen.

"By means of this conception it becomes possible to account for radio-activity without having recourse to what Mendelejev denominates the metachemical and vague theory of electrons. The radio-active atoms, with their high atomic weights, possess, as large centers of mass, the power of holding a relatively large number of ether atoms, although there is no chemical combination. The entrance and exit of these ether molecules from the groups are accompanied by those disturbances of the ethereal medium which cause the rays of light. The phosphorescence of bodies immersed in liquid air is caused by the increased absorption and condensation of ether molecules at low temperatures. The original article contains many other suggestive thoughts, such as the probability of a fifth halogen element, with atomic weight of about three, corresponding to the fifth metal of the alkalies."

This other side of the question of radio-activity and its explanation makes clear how little is really known of these phenomena, which have lately attracted so much attention by both chemists and physicists. It also serves to show the futility of hopes of wonderful curative properties founded upon radio-active materials. As a matter of fact radio-activity is not so uncommon as has been thought, and it is probable that we have been taking into our systems much radio-active material without at all realizing it and without our ordinary metabolism being at all affected by it. Unfortunately, however, whenever there is anything new discovered there will always be those to cry out on the market place that at last the great secret has come and that the mysteries of health and disease are to be obscure no more.

PRACTITIONER.

A very dear old friend of one of the contributors to these Byways asked the other day on what principle was the word practitioner so commonly used as a synonym for physician. The word practitioner has something of a shady meaning among lawyers, implying that its bearer is perhaps not much more than a pettifogger. Is there not at least a shade of this meaning in the word practitioner as applied to a medical man also, and should not the full expression always be used—practitioner of medicine? Long ago, so long that the present generation is not likely to remember much about it, that delightful critic of English, Mr. Richard Grant White, called attention in his "Words and Their Uses," a book which has gone through some seventeen or even more editions, had something to say with regard to this word practitioner.

It is in the chapter on words that are not words in the original edition and runs thus: "Practitioner is an unlovely intruder, which has slipped into the English language through the physician's gate. We have no word practition to be made a noun of agency by the suffix er or ist. But either practitioner or practitionist means only one who practises, a practiser. Physicians speak of their practice, and of the practice of medicine, and in the next breath call a medical man a practitioner. The dictionary-makers give practice as the stem of practitioner—it is difficult to see why. The word is evidently the French practicien, which has been anglified first by distortion, and then by an incongruous addition, in the hope of attaining what was unattainable—a word meaning something bigger and finer than is meant by the simple and correct form practiser."

In one of the subsequent editions of his work Mr. Richard Grant White returns to the word, showing some of the unsavory estimations of it, that it would perhaps be well for medical writers to know who insist on using the term. He says:

"The word practitioner, which has already been remarked upon as abnormal and indefensible, also affords an illustration of the point under discussion. It is not a new word, its use dating back at least three hundred years. Bishop Latimer, according to Richardson, uses

it in his sermon on the Lord's Prayer, applying it to Satan: 'Consider how long he hath bin a practitioner;' and I find it in 'The Gardener's Labyrinth' (Ed. 1586), more than once. For example: 'Sundrie practitioners mixed the bruised leaves of the cypress tree,' etc. (p. 32). We have legitimate words with which the formation of this one seems to be analogous. Wicliffe writes, 'For how manye weren possessioneris of feldis,' etc., and Sidney, 'Having been of old freedmen and possessioners.' I venture to say that Wicliffe and Sidney might much better have written possessors; but still there is a noun possession from which possessioner may be properly formed. So from redemption we have redemptioner, and from probation, probationer. But there is no noun practition, from which to form practitioner, and, therefore, even Latimer cannot make it a normal product of our language. As to my conjecture that it was formed in imitation of the French practicien, I have since found the following interesting and confirmatory passage in Stephen's 'World of Wonders' (A.D. 1616):

"'What reason is it then that Lawyers should make them such good sport for nothing? Or that they should be weary of taking before they be weary of giving? And I am easily induced to thinke, that when they were called Pragmaticiens, that is Pragmatitioners (by the original word), things were not so out of square; but since that a sillable of their name, was clipped away, and they called Practiciens, that is, Practitioners, they knew well how to make themselves amends for this curtailing of their name, as well upon their purses who were not in fault, as upon theirs who were the authors thereof'" (p. 129).

All of which goes to show that the term practitioner, unqualified, has always been in bad odor and that when used seriously as a synonym for physician, which is quite a good enough word for most people, the adjective medical should be added to it so as to avoid any of the innuendos that otherwise might go with its unqualified employment.

RATIONAL AND EMPIRIC USE OF DRUGS.

Some of Sir William Gowers' remarks with regard to the employment of drugs on rational grounds or for empiric reasons only, represents so well the truth in this important matter and at the same time are so full of information of a kind not easily obtained that every physician should have them in his scrap book. They were published in the recent volume of clinical lectures, published in this country by Blakiston, and were reviewed in the MEDICAL NEWS a short time ago:

"The term 'rational therapeutics' is applied to treatment in which a drug is given with success in accordance with preconceived ideas or theory. The theory may turn out quite wrong, although the result is the same. What, then, becomes of the rationality? In empirical therapeutics a drug is given because it is found by experience that in the particular condition it does good. Often we cannot even guess why. But the fact remains, and surely to act upon observed experience is as truly a rational proceeding as is action upon a theory which may be correct or incorrect. After all, the medicinal treatment which can be based upon any definite theory is small. How few are the drugs we can use to advantage which were not discovered by pure experience. In not one drug in twenty of those of most certain service can the use be traced to anything except unguided experiment. Our knowledge of these drugs, derived from the past,—and often from the distant past,—must be assumed to be the result of experiments innumerable, or perhaps continued through the long centuries in which the human race has lived under the need to counteract disease by every available means. The need for food must itself have led to a knowledge of the physiological action of most herbs of the field, and the habits of animals under observation may often have had the force of example. It is probable that since man became able to observe and to reason, every common herb of the field and fruit of the tree has been at some time tested, and thus by slow degrees the knowledge of a physical good and evil has been acquired.

"It is strange, indeed, to note how far back goes the use of the drugs on which we most rely. Most of them can be traced back into the distant past until they are lost in the blue mists which shroud alike the hills of Greece and the deserts of Arabia, or to the time when the world learnt its wisdom from the land where not the symbols of man's thought lie deep beneath the desert sand or stand silent in the cold moonlight of a long dead past. We smile at the popular herbal remedies. But it is to these that we owe the majority of our most useful drugs. I cannot conceive a therapeutist surveying a list of the chief drugs on which we depend in our daily work—and do not depend in vain—without a sense of wonder and perhaps of humiliation. We disinfect out our rooms with burning sulphur; and so men did before the time of Homer. We purge sometimes with rhubarb, especially when some subsequent astringent influence is desirable, and so did the old Arabians for the same special reason. The value of castor oil in its chief use was familiar, probably for ages, to the natives of the East and of the West Indies before it was made known in Europe by a physician from Antigua, one hundred and fifty years ago. Aloes was employed in the same way long before the time of Dioscorides and Pliny. The knowledge of the influence of ergot in parturition we owe to the peasants of Germany, and the use of male-fern for tapeworm goes back to the old Greeks and Romans. The employment of mercury in syphilis by inunction and fumigation, which our nineteenth-century therapeutists regard with such satisfaction, seems to go back to the time of the Crusades, and it is said that its use can be traced in Malabar as far back as the ninth century. Podophyllum as a purgative we owe to the North American Indians. If we go through all the drugs on which we most rely we find the same story. Even in the case of those which are the latest additions to our resources, we find that, with very few exceptions, their use arose from what we must regard as pure empiricism. It was by accident that the local anesthetic influence of cocaine was discovered. The unexpected results of a simple experiment afforded us the chief use of antipyrin; and that which is perhaps the greatest practical discovery of modern times in the influence of drugs on disease—the use of bromides in epilepsy—was the result of a chance observation of its use on an allied state—also empirical. Precisely the same treatment is true regarding the employment of iodide in syphilis. It arose from almost random trial of the influence of burnt sponge on goiter. To this day we are without any rational perception of their mode of action. I yield to no one in my sense of the importance of the rational in therapeutics; but we need to be careful lest, in contrasting the rational and the empirical, we allow our esteem for the one to induce a depreciation of the other. We can afford to despise no source or kind of help, nor to permit our estimate to be prejudiced by the many warping influences to which our thought is liable.

"Any attempt to frame a definition of rational therapeutics will, I think, have one effect. It can hardly fail to raise a doubt as to the propriety of considering that a theory to explain an empirical discovery makes the

therapeutics rational. It is very easy to frame a theory of the action of a drug, and it is easy to extend this theory to the nature of the disease in which the drug does good, and at the same time to ignore the many other possible ways in which the effect may be produced, and so to build from an uncertain foundation an edifice altogether unstable. When I recommend a drug I am often asked 'How does it act?' Occasionally I can give some adequate reason, but I am generally compelled to answer, 'I do not know; it is often useful in this condition.' Sometimes I can add, 'There are several ways in which it may act.' Sometimes I am obliged to say, 'I have no idea how it does good.' It has not been my privilege to add much to our therapeutical resources, but the few agents I have recommended have been based on pure empiricism. Many observers have confirmed the statement which I made more than twenty years ago regarding the occasional service of borax in epilepsy. In inveterate cases, which do not yield to bromide, borax sometimes does good that is definite and distinctly greater than that which bromide produced in those patients. But I cannot say why. It was one of the many things I tried, simply as a peasant might try in succession a number of herbs. Further, the diminution in the tendency to the distressing pains in locomotor ataxia, which is caused by the regular administration of chloride of aluminum, is so distinct that I have little doubt that the time will come when this drug will find a place in the Pharmacopœia. But I had no other reason for trying it than the fact that some analogue suggested it. Of the rational we have here no trace, although I should take exception to the difference involved in the application of the epithet 'irrational.'"

A DECALOGUE OF HEALTH.

There are many expresions of older physicians that deserve a permanent place in the scrapbooks of modern general practitioners of medicine, where they would often be seen in order to recall some of the important principles that clinical experience has shown to be of special value. Among these one of the most deserving of a prominent place are the ten good rules of health which were formulated by Dr. Frank H. Hamilton, the distinguished New York surgeon, who was in no sense a narrow specialist, and whose large-minded view of things medical makes his opinion of special importance. He called these rules a decalogue of health, and now that interest very generally is being awakened and the important problem of maintaining health by physical culture and habits that aid nature in her effort to preserve health, the reprinting of them will show that the modern fad, in as far as it does not go into exaggeration, is not something new, but agrees with commonsense opinions of physicians in every generation.

Here then is Dr. Hamilton's Decalogue of Health:

1. The best thing for the inside of a man is the outside of a horse.

2. Blessed is he who invented sleep—but thrice blessed the man who will invent a cure for thinking.

3. Light gives a bronzed or tan color to the skin; but where it uproots the lily it plants the rose.

4. The lives of most men are in their own hands, and, as a rule, the just verdict after death would be—felo de se,—took his own life.

5. Health must be earned—it can seldom be bought.

6. A change of air is less valuable than a change of scene. The air is changed every time the wind is changed.

7. Mold and decaying vegetables in a cellar weave shrouds for the upper chambers.

8. Dirt, debauchery, disease and death are successive links in the same chain.

9. Calisthenics may be very genteel, and romping very ungenteel, but one is the shadow, the other the substance, of healthful exercise.

10. Girls need health as much—nay, more than boys. They can only obtain it as boys do by running, tumbling—by all sorts of innocent vagrancy. At least once a day girls should have their halters taken off, the bars let down, and be turned loose like young colts.

IBSEN AND PSYCHOPATHOLOGY.

Those who are interested in theatrical psychics had another opportunity in the presentation of Ibsen's drama of Rosmersholm by the Century players to see how well the Norwegian dramatist is able to put psychopathological conditions into dramatic form. The story is a comparatively simple one, the climax of dramatic action being brought about by a dominant idea, an obsession that finally works itself in the lives of those who live in the constant presence of the overmastering thought of the suicide of the wife from a bridge that can be seen from the window of the house. Beata, the wife, evidently of not very strong mind, in fact, generally believed to be of less than normal mental powers, in a mingled fit of jealousy and supposed good-will toward her husband, so as to enable him to marry the woman whom she considers he loves, commits suicide. The idea of this death falls like a pall over the old gloomy house, whose possessors have always been of rather melancholy disposition, and it is not lifted by the determined efforts of the nurse whose presence has been the cause of the wife's suicide.

On the contrary, it brings out very clearly what so frequently happens—the influence of a psychic contagion, which finally influences the mind of the nurse and leads her to agree to commit suicide at the suggestion of the husband, who accompanies her to her death. From the very beginning one feels how well Ibsen has realized the power of such a dominant idea, especially with the scene of the death always in view from the drawing room window, and the constant reminder of the awful cloud that hangs over the house. Specialists in mental diseases know how much of influence for evil such an obsession may have and how it may pervert the best intentions and keep people from getting interested in their lifework rather than in this dominant melancholic idea that is so insistently in their lives.

It is a study in pathological psychology that Ibsen has put upon the stage in Rosmersholm. It bears a curious resemblance, which Mr. Huneker pointed out in a recent number of the *Sun*, to the old tragedies of the Greeks, with stern fate and inevitable necessity always in the background of the picture. Mr. Huneker says:

"The protagonist of Rosmersholm, is Beata. She is seldom long absent from each of the four acts. She peers over the edges of the dialogue, and in every pause one feels her unseen presence. An appalling figure this drowned wife, with her staring, fish-like eyes! She revenges herself on the living in the haunted brain of her wretched husband, and she exasperates Rebecca, slowly wearing away her opposition until the doleful catastrophe. There is something both Greek and Gothic in this spectral fury, this disquieting Ligeia of the milldam.

"We find the old hero and heroine obsessed by fate, replaced by this neurasthenic pair. The antique convention is altered, ancient values depreciated. A hero is no longer interesting or heroic; the heroine, a criminal, is no longer sympathetic. Yet we are enthralled by this sinister spectacle, for if cultivated man disdains the crude dramatic pictures of lust and cruelty admired of his ancestors, he, nevertheless, hankers after tragedy. And it is for the modern that Ibsen has devised a tragic, ironic drama of the soul. In doing this the

dramatist is the slave of his own epoch, for to quote Goethe again, a genius is in touch with his century only by virtue of his defects; he, too, must be an accomplice of his times."

Ibsen is perhaps not to be blamed for presenting with such wonderful dramatic force studies of real life. We would not for an instant consider that he is in any way to be identified with his creations. There is real genius in them. It seems very doubtful, however, whether any good can ever be accomplished by such work, and whether, on the contrary, it may not even be a source of harm to the neurotically inclined, who are most apt to be interested in Ibsen. The very feeling of the all-powerful influence of an imperative idea, as brought out in such a play as Rosmersholm, is apt to weaken whatever inhibitory control is yet alive in neurotic natures and make them feel their inadequacy to control the course of what must seem to them as inevitable nature.

MEDICAL BOOKS POPULAR 200 YEARS AGO.

Books Printed for and Sold by William Innys, at the Prince's-Arms in St. Paul's Church-Yard. London.

Anthropologia Nova: or a New System of Anatomy, describing the Animal *Economy*, and a short Rationale of many Distempers incident to Human Bodies, illustrated with above 80 Figures drawn after the life; and to every Chapter a *Syllabus* of the Parts, described for the Orstruction of young Anatomists, by *James Drake,* M.D. In 2 Vols. *8vo.*

The Anatomy of Human Bodies; with Figures drawn after the life, by some of the best Masters of *Europe,* and curiously engraved in 114 Copper-Plates. By *William Cowper, Oxford.* Printed at the Theater, on large imperial paper, in *Folio.*

Pharmacopoeia Extemporanea: or a Body of Prescripts, in which Forms of Select Remedies accommodated to most Intentions of Cure, usually occurring in Practice; together with Virtues, Reasons of Operation, Rules, Cautions, Practical Observations, Manner of giving Doses, a Catalogue of Medicines and Copious Index, are proposed for the Assistance of young Physicians. Done into *English* out of *Latin*, by the Author. *Theo. Fuller,* M.D., with large additions. *8vo,* 1710.

An Essay concerning the Knowledge and Cure of most Diseases afflicting Human Bodies. To which is annex'd a short Account of Salivation and the Use of Mercury. By *P. Poxton,* M.D., *8vo,* 1711.

The History of Cold Bathing, both Ancient and Modern, in two Parts, by Sir *John Floyer,* of *Litchfield,* Kt., and *Edward Baynard,* M.D. The Third Edition, with large Additions, *8vo,* 1700.

Praxia Medica: The Practice of Physick; or Dr. *Sydenham's Proceffus Integri,* translated out of *Latin* into *English*, with large Annotations, Etc., and various methods of Curing the Clap, Running of the Reins, *French Pox,* Etc. The Second Edition, enlarged throughout with some thousands of Additions, not in the former Impression. By *William Salmon,* M.D., *8vo.* 1707.

Pharmacopoeia Bateana: Or, *Bate's Dispensatory,* translated from the last Edition of the *Latin* Copy, Containing his choice and select Recipes, The *Arcana Goddardiana*, Etc. The Fourth Edition. By *W. Salmon,* M.D., *8vo.* 1813.

Phthisiologia: or, a Treatise of Consumption, wherein the Difference, Nature, Causes, Signs, and Cure of all sorts of Consumption are explained. By *Richard Morton,* M.D.

The Anatomy of the Brain, containing its *Mechanism* and *Physiology.* By Dr. H. Ridley, in *8vo.*

D. Guil. Cole Nova Hypothesis ad explicanda Febrium intermittentium Symptomata, *8vo.*

Gualt. Harris, M.D. Morbis Acutis Infantum. 2nd Ed. *8vo,* 1705.

Three *Physico-Theological* Discourses, concerning (1) The Primitive Chaos and Creation of the World. (2) The General Deluge, its Causes and Effects. (3) The Dissolution of the World, and General Conflagration. *8vo.*

The Wisdom of God manifested in the works of Creation, in two Parts, *viz.*, The Heavenly Bodies, Elements, Meteors, Fossils, Vegetables, Animals (Beasts, Birds, Fishes and Insects), more particularly in the body of the Earth, its Figure, Motion and Consistency, and in the admirable Structure of the Bodies of Man, and other Animals, as also in their Generation, etc., with Answers to some Objections. 5th Ed. Very much enlarged. *8vo,* 1709.

Medical Experiments: Or a Collection of Choice and Safe Remedies, Very useful for Families, and fitted for the Use of Country People. By the Honourable *Robert Boyle,* Esq. 4th Ed. Enlarged with a Supplement, *12mo.*

Of the Reconcileableness of Specific Medicines to the Corpuscular Philosophy. To which is added a Discourse about the Advantages of the Use of simple Medicines. By *Robert Boyle,* Esq. *8vo.*

Short Memoirs for the Natural, Experimental History of Mineral Waters. By *Robert Boyle,* Esq. *8vo.*

Blancardi Opera Medica, Theoretica, Practica and Chirurgica, 2 vols. *4to.* With Illustrations.

Hippocratis and Galeni Opera Grae. Lat. 13 Vol. Fol. *Paris.*

Plumier Description of Plants of America.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-Ninth Annual Meeting, held in Boston, Mass., May 24, 25 and 26, 1904.

FIRST DAY—MAY 24TH.

The Society met in the Boston Medical Library under the Presidency of Dr. Edward Reynolds, of Boston.

Address of Welcome.—An address of welcome was delivered by Dr. Charles M. Green, of Boston, which was responded to by Dr. Henry T. Byford, of Chicago.

The Treatment of Gall-stones Found as a Coincidence in Abdominal or Pelvic Operations.—Dr. John G. Clark, of Philadelphia, stated that among the unsettled questions in abdominal surgery, the treatment of gall-stones found as a coincidence in abdominal or pelvic operations might be considered a debatable one. He followed the plan at present of removing gall-stones which were found in the course of another operation, if the patient's condition permitted of this extra operation. Although it was stated that 95 per cent. of gall-stones produced no symptoms, he believed that this statement should not be applied to cases as one met with them at the time of an operation. In his review of recent literature he had been especially impressed with the fact that knowledge of the early stages of cholelithiasis was very indefinite, and that many cases which came to operation for more or less urgent symptoms did not have the clinical symptoms of colic and jaundice, as usually taught in medical schools. In view of this hiatus in the early history of this disease, he believed that many symptoms now attributed to gastralgia, indigestion, functional disturbances of the gastro-intestinal tract, etc., would, as knowledge increased, be ascribed to the presence of gall-stones with associated infection, which was so frequently found in cholelithiasis. In referring to the

etiology of gall-stones, he said that three facts had been prominently established: (1) That the bile was not bactericidal. (2) That the microorganisms in the gall-bladder were predisposing, if not absolute, causative factors in the formation of gall-stones. (3) When gall-stones were present in the gall-bladder, infection in that viscus was much more likely to take place. He mentioned three general avenues through which infection might enter the gall-bladder. (1) From bacteria circulating in the genital blood stream and reaching the liver through the hepatic veins; (2) by the direct passage of bacteria into the common bile duct from the duodenum: (3) by the transportation of bacteria from the intestine through the portal circulation. He then recurred to the frequently quoted statement that 95 per cent. of gall-stones did not produce symptoms, and showed from his own series of cases that in at least 50 per cent. there were varying symptoms from undoubted attacks of colic and jaundice to less pronounced gastro-intestinal symptoms. To justify operative intervention in cases which were not producing well-defined symptoms, the mortality and morbidity should be very low. In his own experience no death had occurred, nor had there been any serious complication referable to the secondary operation. In lieu of the fact that the additional operation did not seriously jeopardize the life of the patient, and also because he had seen two patients die from cholelithiasis a year or more subsequent to an abdominal operation, in which, had the routine exploration been made, the gall-stones might have been easily removed, he believed that the best interests of the patient would be conserved if the gall-stones were removed as a secondary part of another operation, in the event of their being found. He appended the history of 12 cases to his paper, in which the various operative points, as well as the significant facts in symptomatology were elaborated.

Kolalin.—Dr. R. Stansbury Sutton, of Pittsburg, said that gall-stones did not always produce symptoms which demanded or justified resort to operation. If they were encountered during the course of another operation, they had better be removed. There was a remedy, however, which obviated the necessity, in some instances, of surgical intervention, namely, kolalin. He had used kolalin in dozens of cases in which he had held operation in abeyance, and did not have to operate subsequently.

Dr. George M. Edebohls, of New York, had occasion at one time to operate on a woman who presented marked dyspeptic symptoms. In addition, she had movable kidney, chronic appendicitis, and induration in the region of the gall-bladder. He anchored the kidney, removed the appendix through a lumbar incision, pulled the gall-bladder into the lumbar wound, and found the stone about 4 or 5 cm. in length, pear-shaped, and nearly filling the gall-bladder. The attending physician was positive that the gall-bladder did not produce symptoms of stone in it. He would not let him remove the stone from the gall-bladder. A year later he opened the woman's abdomen for some other condition, making an incision near the gall-bladder. He investigated the gall-bladder, found it was perfectly healthy, and that the large stone had either passed or had been dissolved. The treatment after the previous operation consisted of the use of olive oil for about a month, and whether this had anything to do with the passage of the stone, he did not know. At any rate, the stone had disappeared and had left no trace of its former existence.

Dr. A. Palmer Dudley, of New York, emphasized the importance of looking beyond the gall-bladder for trouble. He believed that stones were formed in the liver ducts themselves, and that from a stagnant circulation cholesterin nuclei formed, and that only a small proportion of stones were found in the gall-bladder. He would not hesitate to go into the center of the liver. In fact, in the last case he had, in which the diagnosis of gall-stones had been made by a medical confrere, he boldly went into the gall-bladder, but found no stone. He found the duct dilated; he went five inches into the right lobe of the liver, as far as he could reach with his finger, and packed the liver full with iodoform gauze, put an apron of gauze over it, and the patient was well to-day. He would explore the center of the liver in searching for such deposits.

Dr. Brooks H. Wells, of New York, said that in the last few years he had used practically the same measures as those outlined by the essayist. A number of patients coming under his observation had complained of obscure symptoms, of so-called functional indigestion. In them he found either disease of the gall-bladder, an over-distended gall-bladder from obstruction elsewhere, or trouble referable to gall-stones. By making a small or large incision, as seemed necessary, cleaning out the gall-bladder and draining it, the patients had obtained remarkable relief from the symptoms that were supposed to be due to functional indigestion.

Dr. Seth C. Gordon, of Portland, Me., said that when the abdominal cavity was opened for other purposes, and he was quite sure the patient could stand it, he would examine the gall-bladder thoroughly, and if gall-stones were found, he would remove them. He cited cases in support of this line of reasoning.

Dr. Hiram N. Vineberg, of New York, said that under the influence of the teaching of Kelly he had been in the habit of doing what had been advocated by the essayist, but after hearing a discussion on gall-stones in the common duct and in the gall-bladder by one of the Mayos, he had changed his method. Simply opening the gall-bladder and removing the stones did not effect a cure, as proven by three or four cases that occurred in his own practice. If the gall-bladder was diseased, however, it should be removed.

Dr. J. M. Baldy, of Philadelphia, said that gall-stones existed in the gall-bladder for years without causing any material discomfort, but that when infection occurred they were liable to give trouble. There was not the slightest question but what large numbers of cases of so-called stomach trouble, or chronic indigestion, sooner or later proved to be cases of gall-stones or of gall-bladder disease. With reference to removing gall-stones when operating for some other intraabdominal condition, the surgeon should consider the physical condition of the patient, the surroundings, etc., and as to whether the patient was willing to undergo the additional risk of a second incision for the gall-bladder operation.

Dr. Walter P. Manton, of Detroit, quoted Ochsner as saying that he had tried almost everything in the so-called cases of chronic dyspepsia, without affording relief; yet after opening their gall-bladders and removing gall-stones which were found, the patients were cured. Dr. Manton had seen a number of such cases, and contended that the removal of gall-stones, or the gall-bladder, if diseased, was the thing to do. He did not believe there was any solvent ever invented which would dissolve gall-stones.

Dr. Beverly MacMonagle, of San Francisco, Cal., stated that when the abdomen was opened for some pelvic or abdominal trouble, the operator should investigate the gall-bladder. If gall-stones had been making the patient ill, causing dyspepsia, or if there were adhesions around the gall-bladder, one should operate.

The conditions that arose in the pancreas as a consequence of gall-bladder disease and of gall-stones were serious, and if the surgeon could do something of a prophylactic nature, without adding to the risk of the patient's life, it was a wise thing to do.

Dr. Clark, in closing, said the formation of gall-stones through bacteria had been clearly demonstrated by a series of experiments. He did not believe anyone would strongly advocate operation unless the gall-stones were producing symptoms.

Ovarian Pregnancy.—Dr. J. Clarence Webster, of Chicago, reported a case of ovarian pregnancy. There was a right ovarian irregularly rounded swelling, measuring 7 by 8 cm. There was no evidence of rupture into the peritoneal cavity. The adhesions were recent. Sections of the ovarian swelling consisted mainly of extravasated blood and disseminated fragments of the chorion. No evidence of transformation of ovarian connective tissue into decidua was noted. It was certain that the pregnancy did not start in a Graafian follicle.

Dr. J. Whitridge Williams, of Baltimore, said there was no doubt that ovarian pregnancy occurred, but it was the rarest of all forms of extrauterine pregnancy. In regard to the Müllerian origin of ovarian pregnancy, he was not quite convinced of it. While there was no doubt that Müllerian tissue might be found in the ovary, as mentioned by the essayist and confirmed by numerous observers, he thought it was going too far to advance that view in explanation of every case of ovarian pregnancy.

Dr. John T. Thompson, of Portland, Me., referred to a case of ovarian pregnancy he had reported at a previous meeting of the Society. He called attention to the nature of the structures in which pregnancy occurred, and to the frequency with which rupture might occur in the early days.

Dr. Edward P. Davis, of Philadelphia, removed an ovarian pregnancy about a year ago, the histology of which had not been completely worked up as yet, although a diagnosis was made very early of the nature of the tumor from the enlarged ovary. The indications were that the pregnancy did not originate in the Graafian follicle.

Dr. Lapthorne Smith, of Montreal, had diagnosed ectopic pregnancy by the clinical symptoms; had operated, and found hematoma of the ovary. He had said to his students that he was sorry that his diagnosis was wrong, because authorities maintained that there was no such thing as ovarian pregnancy, but after hearing what had been said he was convinced there was.

Uretero-lithotomy.—Dr. J. Wesley Bovée, of Washington, D. C., in a paper on this subject, gave the history of the operation, and then discussed the size and number of calculi. The routes for reaching and extracting ureteral calculi, he said, were the transperitoneal and the extraperitoneal. The latter might be subdivided into loin, inguinal, vaginal, rectal, sacral, perineal, and transvesical. The transperitoneal route should never be the one of election, as the danger of peritoneal infection from the urine was too great. Of the extraperitoneal routes, the selection would depend largely upon the location of the calculus or calculi, although the operation of Ceci of removing it through the rectum should only be considered justifiable when the stone had practically sloughed through into the rectum. In a class of cases characterized by the stone having been lodged in the intravesical portion of the duct and later sloughed into a pocket in the bladder wall, which it had made for itself, the vaginal and inguinal routes were the only safe ones, although in so stating he was not unmindful of the number of cases in which suprapubic cystotomy had been done. He discussed the removal of the calculus from the ureter, and the methods for so doing; also the treatment of the ureteral opening. Speaking of drainage, he stated that all ureterolithotomy wounds should be drained. This was because the urine was practically never normal, therefore rendering wound infection probable. The possibility of urinary leakage subsequent to operation afforded another positive indication for drainage.

Nephrectomy for Primary Tuberculosis of the Kidney.—Dr. Hiram N. Vineberg, of New York, read a paper on this subject. Tuberculosis of the kidney, both primary and secondary, was more frequently met with in women than in men in the proportion of about two to one. It was different from what occurred in men; renal tuberculosis in women was rarely associated with tuberculosis of the genital organs. A cystitis in women that resisted the topical applications of the silver nitrate solution by the Kelly method should be looked upon with marked suspicion as being of tuberculous character, even though repeated examinations of the urine should show an absence of the tubercle bacillus. The differential diagnosis of a non-tuberculous from a tuberculous cystitis with the aid of the cystoscope was not as reliable as the therapeutic test outlined in the preceding sentence. Pronounced reddening or ulceration about the mouth of one of the ureters, with absence of other bladder changes, was held by some authorities as pathognomonic of tuberculosis of the corresponding kidney; while the sign was an important one, too much weight should not be attached to it in women. In most cases the removal of the diseased kidney would bring about practically a cure of the descending cystitis. He doubted the wisdom of the advice to cure the cystitis before undertaking the removal of the kidney. In women, owing to the fact that the disease was most frequently primary and unilateral, the modern tests for determining the functional capacity of the second kidney were not as essential as in men. Catheterization of the supposedly healthy kidney was a procedure to be avoided, when, as was frequently the case, there was associated a tuberculosis of the bladder. The prognosis of nephrectomy in renal tuberculosis in women was exceedingly good. Of the writer's four cases operated upon, seven, five, two, and one and a half years ago respectively, all were alive and in good health.

Dr. Joseph E. Janvrin, of New York, reported a case of a woman who had been ailing for two years with what was supposed to be a renal calculus. Before operating, Dr. Willy Meyer examined the woman, and agreed with him that the case was probably one of calculus in the pelvis of the kidney, with possibly calculi in the ureter. The kidney was removed, and it was found that its pelvis was infiltrated with tuberculous deposits in the very early stage. The patient made a good recovery and was well to-day.

Dr. J. Wesley Bovée said that if one read the proceedings of the late meeting of the German Congress, he would be impressed with the comparatively large proportion of cases in which primary tuberculosis was found in both kidneys, or the very small proportion in which one kidney alone was involved. As to the indications for operation on tuberculous kidney, the surgeon should be sure that the opposite kidney was capable of carrying on the function of excreting urine for the whole body before he decided to remove one tuberculous kidney. A nephrotomy might be done, and the kidney most markedly diseased drained, without taxing the other kidney to a great extent. As regards cystitis in tuberculosis of the kidney, it was a late, not an early, symptom.

Dr. Philander A. Harris, of Paterson, N. J., said that in cases of tuberculosis of the kidney it was difficult,

where the bladder was corrugated and changed by the pathology present, to find the ureter; but by painting the entire field of the bladder with some solution sufficiently colored with a swab, as Prussian blue, he had succeeded in finding the ureters in the case of a girl which he could not otherwise locate.

Dr. Seth C. Gordon operated on a man, removing a kidney which was situated low down in the abdomen, painful, and bound down by adhesions. The patient died eleven days after the operation, and post-mortem examination showed that the man had no other kidney. Two years afterward he removed a very large kidney from a woman, who lived twenty-eight days after operation. For twelve hours she did not have a single uremic symptom, nor was a drop of urine secreted, and she died in full possession of her faculties. Post-mortem examination revealed that she had no other kidney.

Dr. J. M. Baldy said it was not uncommon to have medical men in the wards of the Policlinic ask if the ureters had been catheterized in the cases of supposed kidney disease, and not infrequently a perfectly healthy kidney was palpated and found on one side which utterly failed to secrete with the patient under an anesthetic or without it. In some instances this failure on part of the kidney to secrete was undoubtedly brought about by the influence of the anesthetic. At any rate, anesthesia would reduce the quantity of secretion very materially. He had had exactly that same experience a number of times in patients whose ureters he had catheterized, but to whom no anesthetic had been given.

Dr. George M. Edebohls said that some four or five years ago he read a paper on "The Other Kidney and Contemplated Nephrectomy." In it he advocated that before removing a kidney an incision should be made on the opposite side to determine by actual inspection and palpation, first, the presence of another kidney, and, second, its probable health, so far as could be determined macroscopically, before removing the diseased kidney. In spite of the advance made in diagnosis, and its limitations in kidney diseases, he had adhered to that rule in all nephrectomies performed since that time, and in one case he had saved a woman's life by so doing.

Dr. J. Riddle Goffe, of New York, reported a case bearing on the removal of the ureter in connection with tuberculosis of the kidney, the patient having been operated on by him in 1896. She was a woman, twenty-two years of age, who had a very large tuberculous abscess of the right kidney. He removed the kidney and three inches of the ureter. She made an excellent recovery, excepting that she had a sinus which lasted four months and then healed. Patient was now a graduate nurse and in perfect health.

Dr. Edward Reynolds, of Boston, gave his experience of 10 nephrectomies for tubercular disease, 7 of them being complete nephro-ureterectomies, all successful, so far as operative mortality was concerned.

Hypertrophies and Inflammations about the Urinary Meatus.—Dr. Robert L. Dickinson, of Brooklyn, read a paper on this subject, saying that their frequency, and the suffering caused gave them an importance out of all proportion to their minute size. Overlooked because hidden among folds of mucous membrane. They were explained by embryology. A tiny ribbon ran from the rear of the vaginal opening forward, on each side of the vaginal and urethral openings, across the vestibule to disappear beneath the clitoris. This fold was persistent in those cases where the hymen ran forward of the meatus, or the meatus seemed to open on the anterior vaginal wall. This fold was enlarged by friction or traction to produce flaps or labia, hanging out each side of the meatus. They were found only with corrugated labia. Dilated or dilatable urethra often accompanied them. The urethal glands opened near the apex of the flaps. They were long, running down into the anterior column of the vagina. Swelling from infection differed from hypertrophy. The cure of chronic inflammation was only feasible by obliteration of the glands. A fine probe passed to the bottom of the gland rendered the vestibular-vaginal surface tense; the cautery wire cut out the probe. For piles of the meatus, the cautery wire was used after cocaine; for prolapse or dilatation of the uretha, resection of the anterior vaginal wall or paraffin injections into the urethrovaginal septum produced a sigmoid profile.

Surgery of the Female Urethra.—Dr. Ely Van de Warker, of Syracuse, N. Y., read a paper on this subject. The urethra, he said, appeared like an insignificant part, its vital relations were negligible, its anatomy was relative, and acquired its importance from its related organs, but it might be said to epitomize a large share of the suffering that woman's pelvic organs inflicted upon her. The amount of disturbance caused by a simple irritation of the urethra to the bladder and indirectly to the kidneys afforded striking proof of the validity of reflected nervous disturbance. The term sacculation was regarded as better than the old one, urethrocele. Its major cause was mechanical, as inflammation alone was not adequate to its production. The urethra might be said to belong to the perineal rather than the pelvic zone of organs. The walls of the canal depended in a measure upon the support of the perineal body. It was often associated with long-standing rupture of this part. Restoration of the perineum was therefore essential to treatment of the sacculation. When large, an elliptical flap of the walls of the urethra was removed and the edges brought together by fine silk sutures. Prolapse of the mucous lining of the urethra the author had generally associated with long-standing urinary troubles of various kinds. It was therefore probably due to a gradually progressive condition, and was a typical ptosis, and complied with the general law of genital prolapse. After removing the prolapsed portion there was a marked tendency to recurrence unless the conditions which gave rise to it were treated and cured. Bladder incontinence and dribbling were often lifelong conditions. That this was due to a defective action of the sphincter vesicæ was more than doubtful. Dribbling was one of the symptoms of hysteria, of which a striking case was given in illustration. Narrowing, by operation, the bladder and end of the urethra, linear cauterization at this point, had afforded relief. Any treatment was liable to fail, and relapses were frequent. The powerful influence of hysterical disturbance over the urinary tract was constantly observed. Dribbling was the related phase of retention. The treatment of this form was more satisfactory. The urethral stricture, when of small caliber, was frequently found with dysuria and dribbling. The author referred to but two cases of urethral mucous polypus and concluded that they must be rare. These growths ought never to be twisted off, as the tissues were too friable. Removal of the growth through the mucous membrane, so that no stump was left, was the proper procedure. Stricture of the urethra, in the author's experience, is common in women. Any condition that tended to produce linear or annular thickening thus led to stricture. Specific urethritis might produce stricture, but it was not the frequent cause alleged by some writers. Stricture of large caliber might be located and measured by the Otis bulbs, but never by the sound, as was recommended by old systematic writers. Annular stricture of the meatus was the form most commonly met with. These ought to be incised and made to heal in an open condition by the frequent passage of the sound. Dilatation alone was

too painful and required too much time. As to eversion of the mucous membrane at the meatus, its prototype was the fusiform stricture of Otis, and its surest cure was by dilatation. Caruncle of the urethra was a common occurrence. Removal, involving the whole thickness of the mucous membrane, being careful not to leave a stump, was an effectual cure.

Pyelitis Complicating Pregnancy.—Dr. Edwin B. Cragin, of New York, said the occurrence during pregnancy of a marked rise of temperature, with pain and tenderness on the right side of the abdomen, was always a source of anxiety to the obstetrician. Although several able articles describing the condition had appeared, it was not generally recognized that pyelitis was a not infrequent cause of the above symptoms. It might be confused with appendicitis, typhoid fever, or salpingitis. It occurred almost, if not quite, invariably on the right side. It was due to pressure on the ureter by the pregnant uterus plus an infection. This infection was usually descending, and was usually due to the colon bacillus. The urine was acid, contained at first albumin and perhaps a few casts, soon followed by pus and bacteria. The prognosis was usually good. Induction of labor was seldom indicated. The medical treatment by urotropin, or allied drugs, with ice-bag over the kidney, fluid diet, and large draughts of water, was usually sufficient.

A Second Case of Puerperal Eclampsia Successfully Treated by Renal Decapsulation.—Dr. George M. Edebohls, of New York, said the first case, reported to the Society a year ago, illustrated the immediate cure by renal decapsulation of puerperal convulsions, recurring with great and increasing violence after the birth of the child, a period at which the hitherto final resource of force delivery was, of course, no longer available. In presenting the case the opinion was advanced that resort to renal decapsulation in the undelivered woman suffering from puerperal eclampsia might obviate the necessity of forced delivery. The case now reported illustrated the correctness of that opinion. Renal decapsulation was performed upon a woman pregnant near term, suffering from puerperal eclampsia, and almost complete suppression of urine. The convulsions were arrested, the flow of urine was re-established, and a threatened death from uremia was averted. Two days after all this had been accomplished labor began spontaneously, and living twins were born. One child died soon after birth. The second child and the mother were in perfect health four and a half months after the termination of pregnancy. Renal decapsulation thus became the rival of forced delivery in cases of puerperal convulsions of renal origin in the undelivered woman. In puerperal convulsions, occurring or recurring after delivery, it constituted the final resort when all other measures had failed.

(To be Continued.)

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.[1]

Sixth Regular Meeting, held April 20, 1904.

The President, S. J. Meltzer, M.D., in the Chair.

Members Present.—Burton-Opitz, Calkins, Gies, Hiss, Hunt, Jackson, Lee, Levene, Lusk, Meltzer, Murlin, Norris, Park, Richards, Wadsworth, Wallace, Wilson, Yatsu.

Members Elected.—J. J. Abel, E. G. Conklin, A. R. Cushny, C. B. Davenport, W. H. Howell, L. B. Mendel, T. H. Morgan, F. G. Novy, W. T. Porter, L. B. Stookey, W. H. Welch.

Constitutional Amendment.—The following amendment was added to the Constitution by unanimous vote: "Each non-resident member shall be required to present in person, at least once every two years, a communication containing the results of an *experimental* investigation, or to send to the President, within that time, such a communication for presentation at a regular meeting of the Society."

Eligibility to Membership.—Many inquiries regarding admission to membership in the Society have recently been addressed to the Secretary. It seems desirable to state publicly that only *active investigators* in biology or medicine are eligible to membership. The Constitution of the Society provides for *automatic forfeiture of membership* by any member who may cease to be an "active investigator, *by experimental methods,* in biology or medicine." Visitors are welcomed to the meetings.

ABSTRACTS OF THE REPORTS OF ORIGINAL RESEARCHES.

On the Secretion of Human Bile.—By P. A. Levene, W. G. Melvin and B. Michailovski. The bile was obtained from a patient with a biliary fistula. The patient had been operated upon for gall-stones, and was in comparatively good health at the time of the experiment. Attention was directed to (1) the influence of diet on the quantity of bile secreted per twenty-four hours; (2) the permeability of the biliary ducts for certain substances like methylene blue and sodium salicylate; (3) the influence of these substances and of some salts and acids on the secretion, and (4) on the nature of the so-called "bile mucin." The quantities of bile secreted under different conditions, together with other data, are briefly summarized below:

Diet and Dosage.	Volume in 24 Hours.	Total Solids.	Organic Residue.	Ash.
	Cubic Centimeter.	Per Cent.	Per Cent.	Per Cent.
Mixed diet.....	780	1.57	0.76	0.82
Animal diet.....	785	1.68	0.60	1.08
Milk diet.	845	1.61	0.56	1.05
Vegetable diet.....	835	1.64	0.80	0.84
Sodium carbonate.	461	1.62	0.71	0.92
Muriatic acid.....	461	1.53	1.08	0.45
Calcium chloride...	687	1.63	0.50	1.08
Sodium salicylate..	642	1.40	0.42	0.98
Methylene blue....	864	1.58	0.54	1.04

For methylene blue and sodium salicylate the bile ducts proved less permeable than the kidneys. There was observed a marked increase in secretion after subcutaneous injections of methylene blue. The "mucin" was found to be a phosphorized proteid, but no purin bases could be detected in its molecule.

Experiments with Certain Nitriles and Their Antidotes.—By Reid Hunt. Experiments (carried out in the laboratory of Prof. Ehrlich) on the toxicity of a number of nitriles, and the antidotal action of certain sulphur compounds toward them, were described. Most of the nitriles studied are poisonous in virtue of the HCN which is split off in the body; in the case of some of the nitriles of the aromatic series and of certain amino nitriles, the molecules themselves seem to be poisonous. Although each of nearly all of the compounds studied is capable of splitting off one molecule of HCN, it was found that the toxicity of the various compounds differed greatly. The toxicity depends in general upon the ease with which the HCN is split off; in some cases this seems to bear a relation to the ease with which the residue united to the CN group is oxi-

[1] Proceedings reported by the Secretary, William J. Gies, Ph.D., of New York. The authors of the reports have furnished the abstracts. The Secretary has made only a few abbreviations and minor alterations in them.

dized in the body. Benzonitrile, containing the group C_6H_5, which is oxidized with difficulty in the body, is scarcely more poisonous than phenol. Acetonitrile, also containing a group, CH_3, which is oxidized with difficulty, is also but slightly toxic. Propionitrile and formaldehydecyanhydrin, which contain easily oxidizable groups, C_2H_5 and CH_2OH, are very poisonous. The toxicity of the molecules of a few nitriles is greater than that of HCN itself, although the latter was the only toxic agent involved. Thus, the molecule of chloralcyanhydrin, $CCl_3CH(OH)CN$ is nearly twice as toxic as that of HCN. The probable explanation of this is that the chloral residue with which the CN is in combination causes this compound to be distributed especially to the central nervous system; the HCN is thus split off in greater concentration in these important organs than is the case after the administration of a compound which is distributed more uniformly to important and unimportant organs. Through the application of this principle it may be possible to modify the distribution in the body of a remedial agent, so that the active principle may be present in especially great concentration in the organs which it is desired to affect. It was suggested that the powerful action of nitroglycerine upon the blood vessels may be explained on a similar hypothesis. The view of Hay, that the dilatation of the blood vessels caused by nitroglycerin is due to the formation in the body of nitrites from this body, has been generally accepted, although the objection has been made that it requires two hundred times more sodium nitrite than nitroglycerin to produce a given effect. This criticism may be met by the hypothesis that the glycerin residue of the nitroglycerin causes this compound to be distributed especially to the arterial walls, so that the nitrite will be formed in greatest concentration at the point where it exerts its action.

The work of Heymans and Masoin on the antagonistic action of sodium thiosulphate toward certain nitrites was extended to many new cyanogen compounds. In addition to the thiosulphate, several other compounds containing a sulphur atom which is easily split off, were tested (the sulphur unites in the body to form a little poisonous sulphocyanate); the most efficient of these new sulphur compounds were thialdin, carbothialdin and potassium xanthogenate. Great differences in the extent of the antidotal action of these bodies toward the various nitriles were noted. Thus, thialdin, protected against nitriles toward which potassium xanthogenate was without action; toward other nitriles potassium xanthogenate was the more efficacious. Many of these differences can be easily explained on the hypothesis that the various nitriles and sulphur compounds are differently distributed in the body. Unless both the sulphur compound and the nitrile reach the same cells, and unless the conditions in these cells are favorable for the formation of the sulphocyanate, no neutralization will take place.

Especially interesting are the experiments on the antidotal action of alcohol toward certain nitriles. It was found that small doses of alcohol protected an animal against three to five times the fatal dose of acetonitrile and formaldehydecyanhydrin, and that after otherwise fatal doses of these substances, the animal recovered if small doses of alcohol were given. It was suggested that the explanation for this action may be that because it is easily oxidized alcohol consumed the oxygen usually available for the oxidation of the CH_3 and CH_2OH groups of these compounds, and for the consequent liberation of the HCN. Support for this hypothesis was found in the fact that dextrose (another easily oxidizable substance) also protects against acetonitrile.

This seems to be the first case in which alcohol has been clearly shown to have an antidotal action toward a poison. It was suggested that alcohol may have an analagous action in certain pathological conditions in which physicians have long claimed a beneficial result from its use. Toward HCN itself and several other nitriles, alcohol has no antidotal action; in fact, in some cases, the toxicity of the nitrile was increased by it.

Toxicity of Certain Quinine Derivatives.—By Reid Hunt. In one of the side-chains of the quinine molecule there is, according to the commonly accepted view, a vinyl group, $-CH=CH_2$. As the toxicity of many compounds (*e.g.*, neurine and allyl alcohol) is chiefly due to the presence of such a group, experiments were made (in Prof. Ehrlich's laboratory) to determine whether this is the case with quinine. A number of derivatives in which the vinyl union was broken by the addition of H (hydroquinine), or of O and OH (oxyhydroquinine), or of H and Cl (hydrochlorquinine), were tested as to their toxicity upon various mammals and certain infusoria. The experiments showed that the presence of the vinyl group in quinine is without special significance as far as toxicity is concerned, the first two of the new compounds being about as poisonous as quinine itself. The results of the experiments with hydrochlorquinine are of special interest; these showed that the addition of H and Cl decreases the toxicity for mammals while increasing it for infusoria. Thus the amount of hydrochlorquinine required to kill mice was two and a half times as much as that of quinine, while the former substance is distinctly more poisonous to certain infusoria than the latter. It is possible that hydrochlorquinine (or similar compounds) will be found to be more effective in the treatment of malaria than is quinine, and further work along these lines may result in the discovery of quinine derivatives which will be of value in certain diseases, caused by protozoa, in which quinine is of little value. Further experiments are in progress.

Report on the Metabolism of a Case of Diabetes Mellitus.—By A. R. Mandel and Graham Lusk. The case was a young man whose urine contained no albumin, little ammonia, only a small amount of acetone and no β-oxybutyric acid. All these symptoms are said to justify a favorable prognosis. The patient was put on three different diets for three successive periods: Diet 1. Rich cream, oatmeal, meats, eggs, butter. Diet 2. Same as 1, with 100 grams of levulose. Diet 3. Rich cream, meat and eggs. The oatmeal was used on account of the favorable results obtained by von Noorden. Diet 3 was practically a meat-fat diet. Upon this diet the polyuria decreased and the sugar fell from 8 to 4 per cent., both of which phenomena would be favorably interpreted by the clinician. But on calculating the ratio between sugar and nitrogen in the urine (after deducting the sugar fed in the cream) the relation between the two was found to be 3.65 grams of dextrose to 1 gram of nitrogen, as follows:

Date.	Dextrose.	Nitrogen.	D. N.
March 2, 1904 ...	82.7	23.0	3.60 : 1
March 3, 1904 ...	87.1	23.8	3.65 : 1
March 4, 1904....	100.7	27.5	3.66 : 1

It will be noticed that the sugar and nitrogen rise and fall together. The amount of fat fed varied but did not affect the ratio. The sugar production is therefore parallel to the proteid metabolism. Since 1 gram of urinary nitrogen represents the destruction of 6.25

grams of proteid we can calculate the sugar production from proteid. This D:N ratio is the same as that obtained in our laboratory in phlorhizinized dogs. It has also been obtained by others in the human subject, but has been falsely interpreted as indicating the production of sugar from fat. It represents the maximum output of sugar from proteid and a complete intolerance for carbohydrates. It is probably the most grievous prognostic sign in diabetes.

A calculation shows that the carbohydrates in the oatmeal and levulose were nearly quantitatively eliminated in the urine when the patient was under the influence of diets 1 and 2. The patient rapidly lost in weight and died in coma five weeks after the completion of the above investigation.

Antihemolytic Properties of the Serum of Nephrectomized Rabbits.—By S. J. Meltzer and William Salant. In studying the properties of the blood of nephrectomized rabbits it was found that bullock's serum, which is distinctly hemolytic for normal rabbit's blood, was less so for the red cells of nephrectomized rabbits. It was found further that the serum of nephrectomized rabbits contains a distinct antihemolytic element which is destroyed by heating for an hour at 58° C. On the other hand, the "washed" red cells of nephrectomized rabbits' blood are at least no more resistant to the hemolytic influence of bullock's serum than the red cells of normal rabbit's blood.

On the Influence of Suprarenal Extract upon Absorption and Elimination, with Demonstration.—By S. J. Meltzer and John Auer. In a series of experiments it was found that a previous intravenous injection of adrenalin will make a rabbit resistant to a surely fatal dose of strychnine. (Such an experiment was demonstrated before the society.) In experiments with subcutaneous injections of fluorescein it was also found that in the animal which had previously received injections of adrenalin, the greenish yellow color of the conjunctiva, mucous membranes and skin appeared much later than in the control animal. Both results might be due to delayed absorption or delayed transudation, or to both. In further studies with subcutaneous injections of fluorescein it was found that the color entered the blood later and in diminished quantity in the adrenalin animal than in the control. Among other observations it was noted that the kidneys of the control animal were colored more intensely than those of the adrenalin animal. The same difference was found when equal quantities of the stain were injected directly into the blood-stream. The lesser coloration of the kidney is therefore due to the diminished elimination by the kidneys in the adrenalin animal. Other related problems are still under consideration. But the reported series of experiments already justify the conclusion that suprarenal extract delays absorption as well as elimination. The starting point for the investigation was the hypothesis, stated by Dr. Meltzer in another publication, that since capillary endothelia possess irritability and contractility their pores are surrounded by rings of contractile protoplasm which act like sphincters upon them, thus increasing and decreasing the permeability of the endothelia. The explanation for the observed facts is now offered that suprarenal extract, which causes a contraction of the smooth muscle fibers of the arterioles, causes also an increase of the contractility of the endothelia, diminishing thereby their permeability and thus reducing their powers of absorption and elimination.

Review—Mendel's law.—By E. B. Wilson. A review of the more important facts in Mendel's observations, together with a statement of some of the deductions to be drawn from them.

SOCIETY OF THE ALUMNI OF THE CITY HOSPITAL.

114th Stated Meeting, held April 13, 1904.

Three Interesting Surgical Cases.—Dr. J. B. Bissell presented three very interesting surgical cases. The first was that of a man who presented a peculiar tumor about the size of a child's head at the right side of the neck. The second case was that of a man about fifty-five years of age who twenty years ago had been operated on for empyema. In succeeding years he had been reoperated, among others by Dr. Weir. The third case was that of a man, an engineer by trade, who presented an obscure new growth on the costal aspect of the body; right side.

Unilateral Right-sided Goiter.—The consensus of opinion was to the effect that the first case was a cystic unilateral right-sided goiter, in spite of the fact that the man stated most emphatically that it had appeared very soon after he had been almost choked while swallowing a piece of meat. It was further agreed that the case of empyema, which Dr. Bissell stated had twenty years ago undergone Eastlander's operation for removal of the ribs for the obliteration of the empyema cavity, was a most remarkable one. True, the sinus had never completely healed, but the man's life had been preserved. The opening had been made in the left anterior portion of the chest midway between the axillary and mammary lines. The heart could be seen beating vigorously against the exposed and much-thickened pericardium, and the sounds transmitted through a stethoscope, the bell of which was placed over this area, were remarkable and instructive. As to the new growths on the ribs of case three, it was uniformly agreed that they must be sarcoma, although it was noted that singularly enough the glands on the left side of the neck were involved, while those on the right side had almost entirely escaped enlargement.

Empyema.—Dr. Guiteras, in discussing the second case, said that the ever-present problem before the operating surgeon was, to wash or not to wash the pleural cavity. Personally he had always washed out the cavity and that immediately after operation, and had never yet experienced any difficulty from so doing. He employs a double catheter and almost any irrigating fluid of a mild degree of strength. Peroxide is safe to use and has a remarkable faculty for dislodging coagulæ.

Dr. G. C. Weiss considered that Dr. Bissell had done the society a great favor in exhibiting this very remarkable case of empyema. It seemed to him in a very broad way to open up the question of whether or not we should resect a rib or endeavor to drain these cases intercostally.

Dr. J. B. Bissell stated that he considered very free drainage absolutely essential. He spoke very favorably of Dr. Bryant's vacuum catheter and of James' bottles. They work on the principle that if you can't pull you may push. He considered that the question in the treatment of these cases was not so much a matter of when to wash or what to wash with as it was how to establish perfect drainage. This case of empyema in his opinion showed that drainage had not been complete, because the fistula had persisted for upward of twenty years.

Dr. A. Moore agreed as to the necessity of free drainage. He exhibited a small instrument which he has had made with the intent of inserting it in the wound which he makes without resecting any bone in order to hold the parts from coaptation and collapse. He said it resembled a Mild's retractor; it is so small that it can easily be buried beneath the

dressings and causes no pain when left *in situ*. In children particularly, if this instrument is put in position and separated with considerable vigor, a very free and adequate opening can be obtained.

Dr. Bissell expressed the belief that adequate drainage could not be obtained by the use of any instrument without resection of a rib or indeed in many cases resection of several ribs. This, the Schede method, is not as satisfactory as the Eastlander, in point of thoroughness. Bryant's tube is an ingenious device which is connected by means of a large piece of adhesive plaster to the wound, the connection being airtight. A Davidson's syringe bulb is passed from here into the pocket of the patient while in another pocket is housed a good-sized flat bottle. Throughout the day, as the patient thinks of it, he pumps this bulb and creates a vacuum in the bottle which is transmitted to the pleural cavity. This device is found in the hands of Dr. Bissell to work admirably.

Miliary Tuberculosis Following Appendectomy.—Dr. J. G. Wells reported a case of this affection in a girl of sixteen. Prior to the attack of appendicitis, which was of the usual acute type, the child was perfectly healthy so far as a very intelligent history could show. At the time of operation, however, she was found to have in addition to her appendicitis a dry form of miliary tuberculosis, the intestines being closely matted together. After some deliberation, the operator broke the adhesions holding these together, sponged the parts freely and sewed up the wound. The immediate recovery of this case was uneventful. In six weeks the abdomen was found to be soft, all rigidity having entirely disappeared, but the patient had a temperature of 102° to 104° F. Three months later, it became evident that she was a victim of general miliary tuberculosis.

Dr. Wells reported a second case. The patient was a child, five years old, a girl in whom a sudden temperature of 105.5° F. had developed. This was followed by sweat and subnormal temperature. It presented all the characteristics of a typical malarial invasion. The blood was, however, free from plasmodia. Leucocytosis, nevertheless, was marked. The skin was yellow. There was tenderness over the hepatic region. Fitz, of Boston, saw her and diagnosed cholangitis. Nothing further was done. Two weeks later she became very sick, and it then was wondered whether or not she had developed a hepatic abscess. Even in the early part of general anesthesia, the right rectus was found to be very rigid. The liver was found to be hard and blue. The gall-bladder was difficult to locate, it being on the posterior wall of the body cavity. Its distention was such that it had reached the size of a large sausage. A tumblerful of thick, creamy fluid was evacuated from it and permanent drainage established. The liver, which had been greatly enlarged, could be seen, under the eye of the operator, to shrink visibly, and within a few moments it had assumed almost normal proportions. There were many interesting pathological problems in connection with this condition.

Dr. T. F. Riley said that this interesting case of miliary tuberculosis added one additional page in the long history of proofs that tuberculosis anywhere in the body, except under unusual conditions, should be severely let alone. One of the most classic positions from which general tuberculosis is known to be induced by operative intervention is in the case of fistula in ano.

Dr. J. B. Bissell had the good fortune to operate on a great many cases of tuberculous peritonitis and had obtained gratifying results, but he makes it a point never to interfere with the adhesions.

Dr. G. C. Weiss reported in most interesting detail the case of a child in whom he had done an ordinary appendectomy. For a number of days after the operation the patient semed to be doing well, but suddenly she began to have a little temperature and almost before her attendants realized it, had developed a serious case of empyema. This was finally located by aspiration and drained by resection of a portion of the eighth rib. Secondary empyemata are rare, except from pneumonic and other infections of the lungs, but from the abdominal viscera one does not ordinarily expect such a complication. It was noteworthy that in this case the temperature went down to normal, forty-eight hours before the operation.

Dr. E. M. Sill said that in his experience this was not uncommon in the empyemas of children. He reported a case of catarrhal empyema in which the tumor was located directly in the median line.

Dr. A. Rupp, in the absence of Dr. Morris Manges, who was to have contributed some "Practical Points of Medical Diagnosis," read a short paper entitled "Paradoxical Measles."

BOOK REVIEW.

Progressive Medicine: December, 1903. March, 1904. Lea Brothers & Company, New York and Philadelphia.

Volume IV for 1903 discusses Diseases of the Digestive Tract and allied Organs, by J. C. Hemmeter; Anesthetics, Fractures and Dislocations, by Dr. L. C. Bloodgood; Genito-urinary Diseases, by Dr. W. T. Belfield; Diseases of the Kidneys, by John Rose Bradford; Physiology, by Dr. Albert P. Brubaker; Hygiene, by Charles Harrington, and Practical Therapeutics, by Dr. H. R. M. Landis. The scope and intention of this work does not need any further characterization, in this place. Practically everything that is of value along these lines is to be found in this excellent quarterly year-book. That which renders it valuable above other works of similar aim, is that more than any other, in our opinion, it shows the results of greater care devoted to making a continued story from a large number of abstracts. In some cases the authors have not been able to free themselves altogether from the purely abstract method, but in most cases the general trend of investigation is related, rather than short clippings of isolated experiences.

With the opening of the present year Progressive Medicine has undergone a certain amount of modification. The publishers have reduced the price, and are supplying it to the profession in a paper cover. This reduction in price brings the work within the reach of everybody. In the first volume for 1904 Dr. Charles H. Frazier gives a very full digest of the recent work which has been done in Surgery of the Head, Neck and Thorax, a very complete analysis of the work in Facial Palsy being presented. Dr. Robert P. Preble writes concerning the work lately done in Infectious Diseases, leaving very few aspects of the subject untouched upon. Dr. Floyd Crandall takes up the Diseases of Childhood, and Dr. C. P. Grayson abstracts the literature of Laryngology and Rhinology, and Dr. Robert Randolph that of Otology.

In its new form the same care and attention to typography are followed as in the old series, the only modification being that of price.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 84. NEW YORK, SATURDAY, JUNE 11, 1904. NO. 24.

SPECIAL ARTICLES.

SOME ASPECTS OF MEDICAL EDUCATION.[1] [2]

BY JOHN H. MUSSER, M.D.,
OF PHILADELPHIA.

IT is no trifling occasion that draws together from the uttermost parts of the country one-fifth of an organization of a profession that is taxed to its utmost in the prosecution of its duties. It is not with sounding trumpets and tinkling cymbals that from the sorrowing bedside—whether in the hovel of the poor or the palace of the rich—from the excitement of the operating room, from the stimulus of the hospital ward or the quiet but inspiring haunts of the laboratory this assembly gathers. That it is possible is a handsome tribute to the noble animus in which are embodied a spirit of inquiry, a thirst for knowledge, a longing for inspiration, a desire to uplift and to be uplifted that pervades the profession. The event is one that should be fraught with the dignity, the inspiration, one might almost say solemnity, befitting a symphonal march. For such animus, fellow members, we have just cause for self-congratulation.

It scarcely need be reiterated here that the spirit which pervades such a meeting is the outcome of that evolution which began with the introduction of precision in medicine. Just as soon as the art of medicine had for its foundation the science of medicine, the possibility of harmonious medical organization arose. When "rule of thumb" or intuition gave way to precision; idealism to realism; when speculation was displaced by fact; when, in short, inductive methods were employed and honest inquiry became the guiding star of action, then harmony could sit in council.

With medical, as with all organizations made up of human elements, it would be only human if not pervaded by the essence of science—truth. Hence with the latter wanting, jealousies and ambitions, self and selfishness would prevail to the end that the true object of organization—a fraternal spirit and conscientious seeking for truth—would be as a flickering flame. A little observation will show that that society, whether county, state or national, that does not have this true reason for its existence, for its guide of action, will be a failure. The reverse is also true that that organization which may be called unsuccessful and unhappy, of snarling men and backbiting colleagues, can be labeled at once as without its true vocation, to the discredit of its members.

The great heights to which our organization is rising rapidly precludes the activities of such as have self for their basis of action, so that each day we see more and more a noble rivalry of its members to do the utmost and the best for the organization; a healthful vying of one another for its welfare. Self and selfishness are looked at askance; partisanship and faction, save for a common end—the welfare of the Association—are memories.

But, fellow members of the Association, at this the fifty-fifth session of our Association we have other causes for congratulation and felicitation. We are on the eve of a union of all the members of the profession in one harmonious organization, each individual of which is willing and proud to consider his fellow a gentleman until he is proved not to be, and not, as of yore, a knave until he is proved to be a saint. We are reaping the rewards of that untiring committee which gave to us this organization with which we now labor. We are prospering beyond measure and gathering a force scarcely to be estimated, in great part as a result of the untiring efforts of the apostle of organization—our McCormack. To say that thirty-four States have adopted the uniform plan of organization, and "that membership in the reorganized States has increased 400 per cent. and enthusiasm," writes our coadjutor, "tenfold more," is enough. We are standing out in our own manliness with the majesty that belongs thereto because of the sentiments expressed when our broadly inspired committee voiced the unanimity of feeling which belonged to the Association, in our principles of ethics. We are letting our light shine through the instrumentality of that genius of medical editors—our Simmons. From five thousand to twenty thousand in less than a decade is a statement of circulation which appals and at the same time arouses a feeling of pride and stimulates to further effort, increased all the more when we reflect that the scientific value of the articles in *The Journal of the American Medical Association* are surpassed by none of its contemporaries; its tone is emulated by all.

Such causes for congratulation bring to this Association greater responsibilities and weightier problems for solution. It is held to be the bounds of this address to indicate responsibilities, some trite and apparently trifling, others most weighty; to point out duties, many so grave and vast, beyond the powers of your official to justly define.

NECROLOGY.

Before passing to the task let us pause a moment and with due reverence take cognizance of our colleagues who have since our last meeting gone to the great majority. The Silent Reaper has been as rapacious as in the past, and more than fifteen hundred fell in his swath. He has spared neither the humble nor the great. The less conspicuous but just as potent laborers in the vineyard can say with the others: "I have fought a good fight, I have finished my course, I have kept the faith."

Of those who have been honored by this Association in the past we lost two ex-presidents, the hearty, rugged, yet withal gentle and kindly Donald MacLean, surgeon and teacher, and the urbane James Farquhar Hibbard, a revered general practitioner and teacher; two ex-vice-presidents in John Bates Johnson, one of the founders of the Association, a great practitioner, an honored teacher, and Isaac Newton Love, genial and magnetic. From the ranks we lost Edmund Andrews, scientist, pioneer in surgery and medical education in the West; George Julius Engelmann, obstetrician, scientist, litterateur, teacher, honored at home and abroad by membership in great organizations; James McFadden Gaston, pioneer in the surgical treatment of affections of the gall-bladder and gall-ducts, an esteemed practitioner; Franklin Staples, Hamilton Atchison West, Orpheus Everts, each obtained prominence and respect by force of character and natural attainments; Emile A. de Schweinitz, scientist and brilliant investigator, laboring not for his own renown but for that of his profession,

passing away at the threshold of a most promising career; Frank Savary Pearce, untiring and enthusiastic, who had been expected to counsel with us this week.

HOUSE OF DELEGATES.

The conduct of business under the new constitution bodes success. The two years of trial have indicated that to the House of Delegates the greatest responsibilities fall. When its members consider the great power the American Medical Association will have for weal or woe in the future and that the great body gives that power almost unstintingly to the delegates, they should justly realize the honor and confidence bestowed on them. With such realization will come honest purpose and deliberate action. All the county and state organizations must appreciate the vast duties to be undertaken and the breadth of view, deliberation and wisdom essential to their correct performance, and consequently select from their number the best of their possessions. Let us as an organization see to it that honor and homage come to those who labor unceasingly in the House of Delegates.

NATIONAL LIFE.

It can be readily seen that an organization of the magnitude and with the object and the spirit of our Association must in justice to itself and duty to its country take part in its social and political life. In order that we can be in touch with such life it would be well for the Association to devote some time to the discussion of broad general topics. We have provided for discussions at this meeting, the advisability of which may be termed tentative. We feel they can be productive of great good, and if the experience on this occasion is the least encouraging, we would urge their continuance. We had hoped to have government officials take up matters pertaining to the relation of the medical profession to the executive, legislative and administrative departments of the government. The exigencies of politics forbade our obtaining the services of those worthy to address this body. All men of political affairs are too busy at this juncture. At other times we may learn with profit from our rulers and law makers. As arranged for this week, so in various parts of the country in which the meetings are held, broad topics of general interest, perhaps with local flavor, could be discussed. From those in the Far West we might learn much of climate or how to conquer the plague or the medical aspect of "the yellow peril." The good judgment of the committee, or the President, can be relied on to select topics suitable to the occasion.

It is needless to refer to the demands that will be made on us by the nation in the future. You will learn through the representatives of the Army, the Navy and the Marine-Hospital Service what is expected of us. My distinguished predecessors, Reed, Keen and others, have pointed out our possibilities for good in the legislative halls of county, state and nation. We must have care never to be partisan or factional toward the weighty matters we will have to decide. We must realize that the power we have may be our undoing. We must realize that we are entering on dangerous ground and that it would better become us to be bidden rather than to intrude ourselves into such territory. Indeed, one may tremble not a little at the possibilities of our development in the wrong direction. So long, however, as we hold true to the spirit which comes out of devotion to science we need not fear.

THE SECTIONS.

The work in most of the sections the past few years bears favorable comparison with that of coordinated organizations throughout the country. To inflict discussion concerning them on this general meeting is, we realize, somewhat of a hardship. Your indulgence is craved, however, for through your medium alone can the sections be reached, while peradventure the work of these sections is fully as important as that of any branch of our Association work. If you will look into it you will find the rise of the Association came with the development of section work. To enhance the value of such work is, therefore, to uplift the organization. The present methods are worthy of trial for a few years just as we should not make haste in changing the new constitution. Regarding it, may we suggest thought along these lines?

1. The continuance of the secretary for a term of years.

2. The collaboration of sections so that one topic can be exhaustively considered at the meeting of the Association without repetition in other sections. For this purpose the officers of the sections should meet for consultation six or eight months before the annual meeting. We feel we did good work by having our distinguished chairmen and secretaries come together last October.

3. The division of the Association into two main sections for work in the mornings, that of (*a*) *medicine*, including pathology, diseases of children, nervous and mental diseases, materia medica, stomatology, cutaneous medicine and sanitary science; (*b*) *surgery*, including obstetrics, gynecology and the more closely related surgical specialties. The members interested in diseases of the eye or nose or throat could contribute to either section the result of any studies related to the respective section. The afternoons could be occupied by the specialized labor of the twelve sections now in existence.

Perhaps it might be thought better to have one morning, at the direction of the Section on Practice of Medicine, devoted to the discussion of general topics related to medicine, in which the entire Association could take part; another morning, at the direction of its secretary, to surgery; a third to the specialties; a fourth to sanitary science. The object is to secure the views of physician, surgeon and specialist on general topics. To instance a subject, as endarteritis, is to call up at once the possibilities for the internist, the surgeon and the specialist.

4. The sections should take up and organize special international congresses when the time is ripe for such meetings. Thus an International Congress of Dermatology could be managed by the correlated section of this Association. With the patronage of the American Medical Association any congress that could command such special energies and broad general support could not fail.

5. The section should name to the President a list of its members from which he could select, when asked, delegates to important national meetings or international congresses.

SANITARY SCIENCE.

The Section on Hygiene and Sanitary Science should receive greater support from the organization. It is the section which must bring us in closer touch with our national life. Through it and those devoted to it we ought to secure greater respect from the body politic, and hence more wholesome power for the welfare of the community. Through it the profession should learn to take greater interest in the work of sanitary officers throughout the country. The valuable address of Billings on "The Relation of Medical Science to Commerce" and that of Thompson on "The Economic Value of Medical Science" indicate the opportunities and responsibilities of the profession. The time has gone by when sanitary positions should be used for

temporary sources of income and obtained by political means. Such offices are growing more and more vital to the public welfare. They have not been attractive because the rewards have not been commensurate wi the responsibility and the labor demanded. They should, we will admit, if looked at from the proper viewpoint, grant large compensation and the occupant should be guaranteed tenure of office not subject to party exigencies but dependent on value received. The fault is partly ours that such is not the case. In but few medical schools is there a serious attempt to educate sanitarians, consequently the physicians who engage in sanitary science in an amateurish way do not give a *quid pro quo*. It does not pay a community to hire them. In one of the large cities of this country it has been impossible for the health authorities to get men who were competent to take up health matters, even though the city was prepared to pay fair salaries. Speculation need not run riot in estimating what would occur in a few years if our universities would give sound practical courses of a broad character, including some engineering, some economics and other features which would round out the man. In preliminary and subsequently in the elective studies the student should not be tempted to go into the special lines of practice. He should have opportunity to go in for sanitary science and perhaps for government service in the Army, the Navy, or other departments. The communities would soon find the worth of men thus educated, and the demand, we would venture to predict, would outrun the supply. In proof of the former, we may cite the fine tribute given to Wende, of Buffalo, by the citizens, *en masse* and of one accord, for the work of self-sacrifice, of unselfishness and of worth as official of the health department. Our Association could as a body and in its constituent parts encourage the medical schools to make such training possible; they could educate the community to demand such services and insist that good compensation is to be allotted for it. The Section on Sanitary Science could take up this as one feature of its work.

But for a more grievous reason, the profession's attitude, there is public disrespect. Survival of the old dictum that a patient's woes are confidential, supports too often the attending physician in failing to realize his responsibility to the community while attending to the welfare of his client. For this, as well as too often for personal reasons, he readily connives with the patient to thwart civic authority, thereby endangering a community. Instead of aiding in securing respect for and obedience to the rules of his sanitary colleague he joins in opposing him. Candor must compel us to admit that too often he fears the advent of the health official may mean some disclosure of his own incapacity. It is fair to say the official on his part is often too ready to give advice, to sneer at diagnosis or rail at treatment. To inspire, therefore, wholesome respect toward these coworkers and establish an *esprit de corps* should be one of the educational prerogatives of this section. Were we to be called to account for duties undone, the sin of not fulfilling our obligation to the community in sanitary matters would doubtless be found the most conspicuous, the one most detrimental to its interests.

Again, if not too insistent, could not this section further educational exhibits in sanitary matters not unlike the superb exhibit last winter in Baltimore, conceived and conducted in the main by our present official of the Sanitary Section? The Association could not do better than issue a grant for the furtherance of this object.

THE SCIENTIFIC EXHIBIT.

It is gratifying to see the interest and success attendant on this new feature of section work. It is another tribute to the belief in the permanent tenure of office of an official when we have the good fortune to get a good one. Attention is particularly called to this exhibit to ask the Association and the other sections to look to the conduct of somewhat similar exhibits. The Section on Ophthalmology showed the possibilities at the time of the Helmholtz anniversaries. When a section takes up a subject let us not have the clinical, pathological and therapeutical aspects alone discussed, but bibliographical and historical features brought out. Let such features be as national as possible. What a fine exhibition it would be to have in connection with, say typhoid fever, a loan collection of the pictures of authors and investigators, of the various editions of their works and of the material things with which they worked, illustrating the evolution of their knowledge of the subject. Who would not be thrilled by a picture of the wards of the old Pennsylvania Hospital where Gerhard worked, of the instruments or materials he worked with, how he lived and what he did; of the first editions of his works, indeed of the manuscript of them? We must confess to a quiver of delight, mingled with reverence, when permitted to handle the manuscript on which Stillé inscribed his communication to the Paris Society. This is not the time or place to indulge in a homily on the value of such exhibits, agreeable though it might be. Through them, as of biography and sculpture and painting, we keep in touch with our history. Foster efforts in these directions, gentlemen of the Association, grant liberally to sections their small demands on you, to the end that you will be stimulating the best instincts in our profession.

THE ASSOCIATION OF LIBRARIANS.

We are not far amiss when we call attention to an organization which in a quiet, unobtrusive way is bringing together the members of the profession on a common ground, where tares do not spring up and thistles do not blossom, but instead in an atmosphere clear, refreshing, invigorating. Jealousies do not thrive in libraries; books soften ambitions. No stronger, more liberal friendships can develop than those that come to book lovers. We owe a debt of gratitude to the Library Association and to its distinguished president, under whose fostering care the influence and power of the Association are unfolding as the hardy rose, exhaling like it a fragrance which cheers and stimulates. Of the many abundant works we owe him, none, we venture, will be more satisfying to him and more lasting for good than the work of the Association of Librarians. This Association should hold not its hand nor stint its heart in upholding its educational efforts.

THE RUSH MONUMENT.

Before this session adjourns, by proper ceremony, graced by the presence of the President of the United States, with an oration befitting the occasion by our distinguished colleague, Dr. Wilson, the monument erected by the Association to the memory of Benjamin Rush will be dedicated. The Association is to be congratulated on the completion of this tribute in perpetual bronze to one of the most distinguished of our countrymen. Not alone should we rejoice on the fruition of this agreeable task, but also because it augurs for the erection in the future of tributes to the memory of others full worthy of our reverence. The invigorating, stimulating influence that comes from having about us our heroes of the past in stone or bronze behooves this Association and its constituent bodies to strain every effort to encourage in this manner hero worship. It is due ourselves to perpetuate the inspirations, the thoughts, the feelings in the counterfeit presentment of our fellows. We are not of those who decry the world

because it has not recognized our Jenner, our Pasteur, our innumerable heroes either by reward in their lifetime or by permanent tribute. We do not begrudge the meed of praise and the plenteous bounty which flow to our warriors and statesmen. It is true, their glory has been attained often by carnage, lives sacrificed to avenge some insult. It was not life that was at stake. It was principle or thought or feeling or, our misanthrope suggests, greed. What countless lives are sacrificed for aspirations; what thousands of innocents for national gain! So, to the actors who stand for such, unstinted regard is given. The public neither appreciates the loss nor the saving of life. Hence, so long as it does not come close to them, civic murders from bad hygienic conditions do not move them. Even when home is devastated they submit to that which they consider mystifying or providential, and merely go their way. They are callous beyond measure to the presence of epidemics. They do not consider for one moment the power they have to assuage the virulence or even wipe out the existence of pestilence. Every effort for amelioration, as we see in tuberculosis, comes from our profession. With such lack of appreciation of their own welfare we need not expect much appreciation from them of our efforts.

In all honesty, we must admit among ourselves, we may not deserve public appreciation. If we realize the truth we may make amends. Could the public be expected to revere and respect when, as usual in the past, perhaps too common now, the profession was divided against itself, not from principle but generally because of pocket, of sordid ambition, of devouring jealousy? Look ye to your county societies! Do the brethren dwell together in harmony? Go to the warfaring court rooms! Do we emerge from them respected and respectful of one another? Until such sores are healed, as they happily will be, when science—and hence liberality of mind and largeness of heart—is furthered by associations like ours, it must remain to us a cherished heritage and privilege to worship our heroes alone. When we learn to respect ourselves, then will we be respected.

MEDICAL EDUCATION.

The object of this Association shall be for the purpose of elevating the standard of Medical Education.

This Association has been, should be, and we trust will be the storm center of legislation for reform in medical education. Since the memorable editorials of Wood in the old *Philadelphia Times*, and the masterly papers and addresses of Pepper and the practical action of the University of Pennsylvania there has been virile progress. In most respects it seems definitely settled as to the course of education a candidate for the degree of medicine should take. Questions of pedagogy are still debatable, but we take it that that student who wishes the quickest returns, the most lasting remuneration, perennial stimulation of the intellect and continuous enjoyment in the pursuit of his labors, should take a college education of three or four years, a four years' course in medicine and, if possible, a hospital internship.

Reference need only be made to the reports to this Association, to the famous report of the majority committee of the Association of American Medical Colleges, to the numbers of the *Journal of the American Medical Association* comprehensively devoted to education, and to many recent admirable addresses in support of the statements.

There is talk about maximum and minimum requirements, about laboratory and hospital courses, the merits of didactic and clinical teaching—a mass of material brought forth from the viewpoint of the educator, or looking to the welfare of the medical profession. We do not minimize the value of such lines of discussion. It has brought us to the position we have attained. But what of the medical student? Should we not look at education from his point of view? Is he quite able to decide whether he should take up the profession of medicine? We hold that a great duty is due the aspirant for medical honors from teacher and practitioner. It is a kindness due him to point out the best methods of securing such education as will yield him results commensurate with the time and expense required. It would be a greater kindness to be enabled to show him that by reason of intellectual temperament or of physical or moral qualities he is not likely to reap the rewards he is anticipating.

The large majority of medical students do not have a good reason for studying medicine. They are ignorant of the mental and physical demands made on them. They are attracted by an uncertain glamour and a specious glory, and heedlessly they go in. The failure of a large percentage of graduates in medicine to acquire more than a bare existence, and too often not even that, proves that they were not educated properly, not fitted temperamentally or physically, to pursue its duties. Should they not have opportunity for learning of the responsibilities and difficulties, rather than to have the brighter phases glorified? Would it not be well to have in our college curriculum a course of lectures for the student who contemplates entering a profession, pointing out the rocks and shoals in his prospective career? An eminent practitioner, not connected with medical schools, would light up and darken the pathway in due proportions. Then, too, should not, as in the Army and Navy, some physical tests be required? The trophy is to the robust, and sad will be the career of the man who is physically handicapped.

If there were any doubt about the value of a college degree to a man entering the medical profession it could be set at naught since the report of the Mosely Education Commission. Quotations like the following, while not pertaining to medicine alone, the result of extensive inquiry and mature deliberation, supported by the statistics they give, uphold the contention of a large employer, that "for 99 per cent. of the non-university men, it is hopeless to expect to get to the top." One opinion they express is that "there is still room for the boy of marked ability 'to come through,' but that his difficulties are greatly increasing, and that, useful as he is, his usefulness would have been greatly enhanced had he had the benefit of a college training." Still another commissioner reports that while only "one per cent. of the entire population of America has received a higher education in her colleges and universities, this one per cent. holds more than 40 per cent. of all positions of confidence, of trust and of profit." It is well known that the "geist" of the individual brings success, for which they say "it is recognized that the educated man takes in a wide horizon and puts more 'soul' into his work."

The essential of success in any department is diagnosis, which requires powers of intellectual penetration and discrimination. President Thwing has again forcefully urged that "the reasoning of the mathematics—and mathematics is only reasoning—tends to promote *clearness* and *accuracy in perception, inevitableness in inference*, a sense of logical *orderliness*. The study of the languages represents the element of *interpretation*. The study of history means the interpretation of life." Are these not the main studies of a college education? While they may promote scholarship, they surely cultivate thought. It need scarcely be pointed out to this

audience that to be a thinker is the salvation of the physician.

To the plea that the acquirement of a college degree takes up too much time and requires too much money, the material answer can be given from other sources to the effect that "the men whom you are surprised to find holding such important positions in factories, though not much over thirty years, are the very men who did not leave the technical college till they were twenty-three or twenty-four; the graduate may have been twenty-five before he donned a jumper, but in five years he learned more with the college training he had as a foundation than the regular journeyman of fifteen years of actual work in the shop." The experience of teachers who have watched the alumni agrees in that the college graduates get quick returns and soon acquire a position of independence.

The poor boy, therefore, need not be deterred, for if he has the spirit and energy to work his way through four years, two years or three years more will be but very little in the final summing up. If the student only knew that the purchase of the best education, whether reckoned in time or money, was the most economical investment, in that as to the former, a thorough education at first is time-saving in later years, and as to the latter, the money outlay is returned more quickly, in more immediate work and larger pay.

There should be one educational requirement—the equivalent of that for which a first-class college degree stands, whether received at a high school or university.

After entering the medical school with, it is presumed, the proper educational attainments, his career the first year should be closely watched. That school has too many students if it does not have enough instructors in the first year to be able to judge with a reasonable degree of accuracy of the character and moral stability of the men. This is not to be taken in a prudish sense or with too critical a scrutiny of habits which are the overflow of the animal spirits or the expiring exuberance of the boy approaching manhood. This can be said that a student who does not play fair in his exercises, who cheats in one demonstration or evades another, who does not show manliness, frankness and truthfulness in his first-year duties, will not be a good diagnostician. He will cheat himself; he will cheat his patient. The teachers of the first year, or at least the second, should know this and block the student there and then. It would be a kindness. Let us then agitate whether we should not have a certificate of manliness, a certificate of health as well as a certificate of mental proficiency, before we admit students to our medical schools or permit them to go beyond the first year. Let us not be decoys, alluring them on to later destruction, but rather be guardians, wrapping the strong arm of experience about them to lead them to the fitting pathway.

Having permitted the student to pass further in his pursuits, we still owe him much. We must see to it that such course is given him the first two years of his student career that he will acquire such fondness for the science of medicine, such reverence for the exploration of its truths, that until his dying day devotion to it will be his stimulus and solace. As a corollary, we must insist that medical schools secure the best men in the market for these places and pay them salaries commensurate with their ability—good living salaries.

It is in the first and second years of his career that the foundations are laid whereby the student becomes the medical thinker. To quote again: "The power of thinking should not be of a base and barren character. The thinking should represent and be concerned with a fine and rich content of knowledge. It should have the exactness of intellectual discrimination; it should have the fulness of noble scholarship; it should embody a culture which is at once emotional and esthetic and ethical, as well as intellectual."

That a desire to relieve suffering, to extend sympathy, to save life, is the impulse of the physician, we all admit, but where is the man among us who will not also admit that a scientific habit more quickly brings it about and more surely sustains and fortifies the humane instinct through the trials and tribulations of exacting practice? That prosecution of professional duties soon becomes commercial that does not have for its basis a true spirit of scientific inquiry. How miserable must that life be which conducts an exacting, drudging, daily routine with only material reward in view. Few are the practitioners who have this sordid view; we can be as sure medicine would soon be forsaken if this viewpoint alone were considered. Hence in the laboratory of the first two years must be aroused and fostered the stimulus for lifework.

The final years should be clinical years, and the last should be in a hospital. The medical school that allows its students to think such opportunity is not due them is most unfair to them. As our schools are now constituted, most of them can not give such requirements. The students should know, however, such requirement is necessary. What has been said regarding the preliminary college education applies equally forcefully to the hospital training. He is thrice armed who enters the arena thus equipped. Medical schools that cannot give such education are cruelly unkind and unjust to the students by having them think it is not essential. Medical colleges that pass off a hospital training for one that is not truly such, fake their students. The student who pays well for his training has the right to demand such as to fit him for immediate action.

It is not the fault of the medical school alone that he can not get it. The public that cries out when there is mistake in diagnosis, fault in treatment, and that shakes its head at the deficient education of our students, must share the blame with the medical school. The public admits that its individual members may at any moment almost be at the mercy of a half-educated physician. It is not necessary to recount, for it is well known, how on land or sea, by day or night, some event may arise in an individual life, the care of which may mean life or death. Even with this knowledge they withhold means to relieve themselves. They admit the necessity of a hospital training. But they, and particularly the public in control of hospitals not used for teaching, say each medical college should have its teaching hospital. They do not appreciate that to give an education which involves a hospital course would require an expenditure of $500 a year for four years by each student. It has been estimated that the cost of maintaining a plant and paying salaries sufficiently large to accommodate 600 students would require the above outlay by each student. Unfortunately, it is impossible to expect students to pay such figures, as it would render entrance into the profession almost prohibitive. It is manifestly impossible, as medical schools are constituted now, to educate all the students of the land properly. Hospital training can not be given except by a few favored institutions, because the doors of hospitals are closed either by the governing body of the hospital or by the teachers in the medical schools.

We believe, personally, if a decree should be issued that no medical school, including its hospital, should exist except on the fees derived from students, but little hardship would follow. The lessened supply of students would increase the demands on the practitioner, so that larger returns would follow. The poor student would sacrifice and strive to get a degree, knowing then

he had a good asset. A diminution in number and an increase in quality is demanded alike by the public and the profession. Such diminution in number would mean that the student would get back his investment quicker and in larger amount than at present, hence good men would be attracted. If we could abolish sentiment for sense and educate accordingly, there might be betterment all around. As it is now, medical students receive part of their education through the bounty of the state or the charity of the public, as such education can only be given in endowed institutions. The public is taxed so that the prospective physician can make a living. Is it right that it should be? Perhaps a mechanic should demand such right to make his son a good workman. We must all admit it is the duty of the state to educate the youth, so that good citizenship is maintained; we can question whether the state should educate the members to obtain a livelihood.

With the same indifference that the public views an epidemic's march they allow hospitals that are engaged in teaching to suffer for the want of funds. Moreover, they close their doors to the advent of teaching in the hospitals under their control. We must admit those who do not appreciate the true function of a hospital have some ground for their contention. Ruled by sentiment chiefly, unfortunately an impracticable master, they sympathize with the patient who still harbors the belief of old that the medical student is one of a class that prowl about not unlike harpies. The public does not realize the difference in the student of to-day and the student of tradition. We cannot hold to account the governing body of the hospital who has the point of view that it is harmful to a sick person to have them under the surveillance of an alleged student rabble. We must admit some patients become alarmed, particularly in institutions where they know they will have the sympathy of the governing body. An analysis of motive will show that the usual patient who will not allow a judicious amount of clinical demonstration when the sense of delicacy is not offended, is truly selfish, in that there is prevented that increase of knowledge and development of skill whereby suffering of others may be alleviated. A little encouragement from the officials would allay alarm on the part of the patient. The desire to help others is infectious, and when one yields in a word, others vie in the work.

The truth of the matter is that in hospitals in which teaching is carried on, rarely, if ever, do the patients complain. Indeed, it is the experience of those teaching institutions that judiciously conducted instruction is appreciated by the patient. In one hospital we might name most of the inmates are pay patients, giving $7 a week willingly, because they know they are buying the services of the best practitioners in the land—the teachers of medicine—which service they could not get at tenfold the figure. The fact that teaching hospitals are overcrowded, not by the poor alone, but by people independent of charity, shows that clinical instruction is not a bugbear. If the governing boards would know that while a few patients might be alarmed, on the whole most of them would be gratified by the attention paid them, and their sense of rectitude and manliness appealed to by the satisfaction that they are doing some good in enlightening students, so that others could be relieved; that their administration would be stimulated to do work beyond criticism; that the nurses would be aroused to better activity while under the observation of those not connected with the hospital; that the interns would do their very best to have most complete studies of the case, and finally, that the chief in attendance, compelled to do his best at the risk of his reputation, they would gladly open their doors, even at the discomfort of the few, but to the advantage of the many. In short, the hospital should have teaching not to oblige the medical school, but for its own survival and regeneration. The benefits the student derives by the object lesson of an orderly hospital can not be estimated. Will not every member of a hospital board admit that his own character, his own sympathies, have been benefited by his connection with the hospital, even though, perhaps, he has not the advantage of an impressionable age? Can he not see, therefore, how the youthful student can be influenced in thought and character and feeling? He cannot lightly toss aside this responsibility, nor even hide it by putting the onus of medical education on the teaching hospital. Every dollar endowing a non-teaching hospital robs the teaching hospital which is engaged in this larger duty.

It is true a class who are compelled to have hospital attention may not sympathize with this feeling. How can we obtain the confidence of this class? Let us organize such association of prominent people in our teaching centers who will agree to have any operation, any feature of disease witnessed by medical students, at the judgment of their attending physician. It would be well if the individuals of such an organization would agree, first, to undergo hospital treatment; second, to be the object of observation by students; third, to have an autopsy performed in case of untimely end. We feel sure that it would be wholesome individually and publicly if each would agree to ward treatment. Such association would rob hospitals of their terror and teaching of its dread. No one can deny that on the whole the public would be benefited from whatsoever point of view we look at it. Indeed, the public ought to learn that disease is an enemy to themselves and their country. Just as we make sacrifices in time of national warfare, so we should be willing to make sacrifices in the daily battle for life. Just as aristocrat and plebian, landlord and tenant, fight side by side in the former, so they should array in solid phalanx in the latter.

But there are hospitals willing to admit students, and yet the privilege is not availed of. This arises because the teaching force of the medical college is not willing to sink its personality and allow the student to go wheresoever he will for his instruction. Courage and some sacrifice is required perhaps. But, when one thinks of the mighty opportunity and the frightful waste, it is saddening. Every hospital should be a school. The fourth year should be so arranged that the student could avail himself of the advantages of hospitals in the immediate vicinity. Let each teaching body have the students understand what he must see and do, and trust you the true student will see it at the best place and with the best men. He must be accountable, of course, with a rigidity that means the exact acquirement of knowledge. To this end the first two years could be well spent in the properly equipped laboratory university, whether in town or country, the third in the authorized hospital of the school, the fourth in extramural hospital work.

Is it not anomalous that the hospital boards give to the nurses who are to act as aids to the physician the highest opportunities, and yet deny it to those who are to give orders to the nurses? This, of course, arises because training schools are the product of modern thought and have not been trammeled by tradition.

But all this talk of the primary education avails but little if we do not see to it ourselves that education is continuous; that from the day of our graduation, forwards, we do naught but toil, toil, toil. It should go without saying, as a mere business proposition, that unless we unceasingly labor but little of the fruits do we pluck. It is demonstrated in a practical manner,

for when we look about us and find the methods of those of our brethren whose labors are not in vain each one bears the scent of midnight oil.

The development of post-graduate schools, the growth of libraries, the groans of the printing press, the enthusiasm of medical societies, all testify to the spirit of persistent self-education that is abroad. It is not for me to urge further the importance of each of us taking from time to time months for study and reflection. Every active doctor should have his sabbatical year. We dare say, extended observations would support the belief that the gain is one hundredfold for each dollar invested in educational outings, and for every hour thus employed, ten is added to life. To finance a medical man from first to last successfully, we dare say, spend all net earnings of the first five years on self-education; after ten years, 10 per cent. of the annual net earnings for an assistant, continuing the 25 per cent. investment for five years. Health, happiness, increased usefulness to the community, a success, which never comes from eccentricity, equal to doubling capital every five years, would follow.

In the course of our work it is necessary for us to halt from time to time and review. Not alone must our mental storehouse be swept out, refurnished, but we must constantly "jack up," if the term is permissible, our mental and moral machinery. Few of us are there who will not find as our days grow fuller an unconscious tendency to slight our work, to become slipshod, to hurry over matters. It is partly an evidence of overwork. The post-graduate school is the salvation. No obstacle can withstand the continuity of drill, which the earnest of us keep in action. If, to continue the imposition, asked what element of character is perhaps lacking to the greatest detriment to the profession and public, we possibly, one and all, would say courage. This is seen in the hesitancy which members of the profession show in giving an opinion, in advising an operation and in asking for an autopsy. How much confidence is destroyed by the want of free, frank avowal of the physician that he does not know on the one hand, or of clear, precise statement of his judgment concerning a case on the other! The greatest success in life is confidence. How many lives are lost by the worker in internal medicine not advising early and unequivocally an operation for fear he might be wrong in his diagnosis! And how many more are lost because the surgeon lacks courage to do, either because he fears the patient may die and his record be marred, or because he may operate when it is not necessary! We must admit we have had some operations done when they were not required, but let it be said to the credit of modern surgery, we have never seen an operation of such character performed by the right man that did any harm to the patient. On the other hand, the resort to operative procedures early, and in cases that even yet are not considered of surgical relief, has saved lives and lessened suffering to a degree that far overbalances the now and then futile measure. It may be assumed, without contradiction, that every case of bad appendicitis that happens to get well without surgical relief has in its wake three to five that die for the want of an operation. In other words, the pernicious influence of a surgical case that recovers without operation is evident in creating the hope that other cases demanding operation might get well without it.

And the man who does not want an autopsy—not only the centers of courage need stimulation, but too often the entire medical storehouse needs refitting. Something best known to the physician himself, we trust, is lacking in the one who treats an obscure case for a day, six days, six weeks, and then does not want an autopsy. If true to himself, true to the demands of his profession, courage will not fail him. In our mental and physical round-up, we must see to it that courage is given a new backbone from time to time.

But, fellow members of the Association, not alone as members of this organization may we indulge in self-congratulation, but as members of a profession whose limitation knows no bounds, we may join in felicitation. Neither language, nor creed, nor country fetters our profession's munificent sway. The thoughts of Ehrlich, in Frankfurt; of our own Welch or Councilman, of Kitasato, in Japan, are correlated. The knife of Mayo in America, of Robson in London, of Kocher in Berne contributes to the relief of suffering in far Cathay. The founts of Lister's genius and Pasteur's divine inspiration bring countless blessings to England, to India, to France and to Africa. What a stimulus it is to realize that, howsoever small the contribution of the humblest of us may be, its impulse will be felt in climes near and far and ages present and remote! What awe cannot but overtake us when we consider each heart throb we study entwines us to Harvey of two centuries ago; with every percussion tone reverberates the sound of Laennec's voice of a century; with each vaccine inoculation, the simple observation and reasoning of Jenner to stimulate our question and deductions!

We rejoice together and cherish our history, by the warp and woof of which we are woven to the post. What heritage for us and our children! Dead must be the soul that wearies of communion with the spirits of the past; deep must be its slumber on which falls the thought of centuries; lethargic its activities that are aroused not by the deeds of heroic men! "Honor and fortune exist to him who always recognizes the neighborhood of the great, always feels himself in the presence of high causes." We worship together our science, devotion to which brings forth character, smothers egotism, levels pretension, drives our solitude, develops such loftiness of thought which can see that "against all appearances the nature of things works for truth and right forever." Of our art, let us see to it that when the final summons comes it can be said of us, "Greater love hath no man than this, that a man lay down his life for his friends."

THE ASSOCIATION OF SURGICAL LESIONS IN THE UPPER ABDOMEN.[1][2]

BY WILLIAM J. MAYO, A.M., M.D.,
OF ROCHESTER, MINN.;
SURGEON TO ST. MARY'S HOSPITAL.

THE history of medical advance from the empirical treatment of symptoms to scientific expectancy, has been based on the study of death and modern research work. The spirit has been fine, although somewhat pessimistic. The great advances have been along the line of preventive medicine and in the elucidation of problems connected with the etiology of disease.

Surgical progress has been, to a certain extent, through similar channels; the spirit, however, has been one of magnificent optimism. The great advances in surgery have come from the clinical side, modern technic having enabled examination of primary conditions during life.

As a groundwork for the study of medicine the pathological laboratory and autopsy room offer unrivaled advantage, but they teach end results only. Who of us has not admired the precision with which a trained observer makes a diagnosis? A few days later one visits

[1] Oration on Surgery at the Fifty-fifth Annual Session of the American Medical Association, at Atlantic City, June 7 to 10, 1904.
[2] Courtesy of the Journal of the American Medical Association.

the autopsy room and here observes that this almost clairvoyant analysis was correct. At the same time, we must also acknowledge that the patient has not profited; it means a hundred pages of pathology and two meager lines of treatment. How many times do we notice in the autopsy revelation that the original lesion has been but slight, and at one stage easily curable, the pathology present largely the result of secondary complications and terminal infections.

The post mortem has been an institution for years, yet what did we know about appendicitis until surgery led the way, or about gall-stone disease, supposed to be an "innocent post-mortem finding," until operation opened up the field? Did knowledge of extrauterine gestation come from the autopsy? By no means. It was through the surgeon's knife, and why? Because secondary conditions so often mask the original lesion at the post mortem. On the contrary, our understanding of acute conditions causing sudden death has been brought about by dead-house investigations; for instance, fatal hemorrhage and perforation placed acute gastric ulcer on a sound foundation. Not so chronic gastric and duodenal ulcers with late death from complications, cholangitis from gall-stone disease, and chronic pancreatitis from the same cause. These conditions could not be correctly studied, excepting after death from accidental cause, and real progress lay dormant until surgery invaded the field.

From research work we have profited much; we are gaining rapidly by this means day by day; but we can not compare the animal to the man, nor can we always artificially create similar conditions. Like the post mortem, it has its limitations, yet these two fundamental methods have enabled us to advance. Without them we would still be in the middle ages. Now the time has arrived, in the light of these investigations, to view conditions from a new standpoint at a time when the lesion is in its infancy long before the post mortem, while the patent may be benefited and the research work applied to the elucidation of living problems.

The medical man must haunt the operating theater as he has haunted the autopsy room and the laboratory. The times have changed; we must have more treatment and less pathology. It is here that surgery wins its triumphs. We must not forget, however, that to physicians of pathologic training we owe the knowledge which enables us to approach the subject. Courvoisier was the real father of gall-stone surgery. It was Balzer, Fitz, Opie and others who cleared up the pathology of pancreatitis, and surgery followed their lead. It is in the union of the internist and surgeon that progress is most rapidly made, and in the readjustment of science the former will be the architect and the latter the master builder.

Once more the physician and surgeon will come together, and the mistakes of endeavor in new fields will receive timely correction at the hands of the pathologist and experimental worker.

The surgical borderland of to-day lies in the upper region of the abdomen, a locality until recently considered almost purely medical. What are the reasons for this invasion, and have the results justified the attempt?

Surgery must be judged on three grounds: First, the mortality of the operation itself and the question whether this is greater than under the expectant plan; second, the permanence of cure contrasted with medical treatment; third, the question of disability, either introduced by the operation itself or the natural length of time which the healing process involves. On each one of these considerations we must answer yes, and we can go still farther and say that earlier operation would reduce the mortality and increase the permanence of cure and lessen the disability.

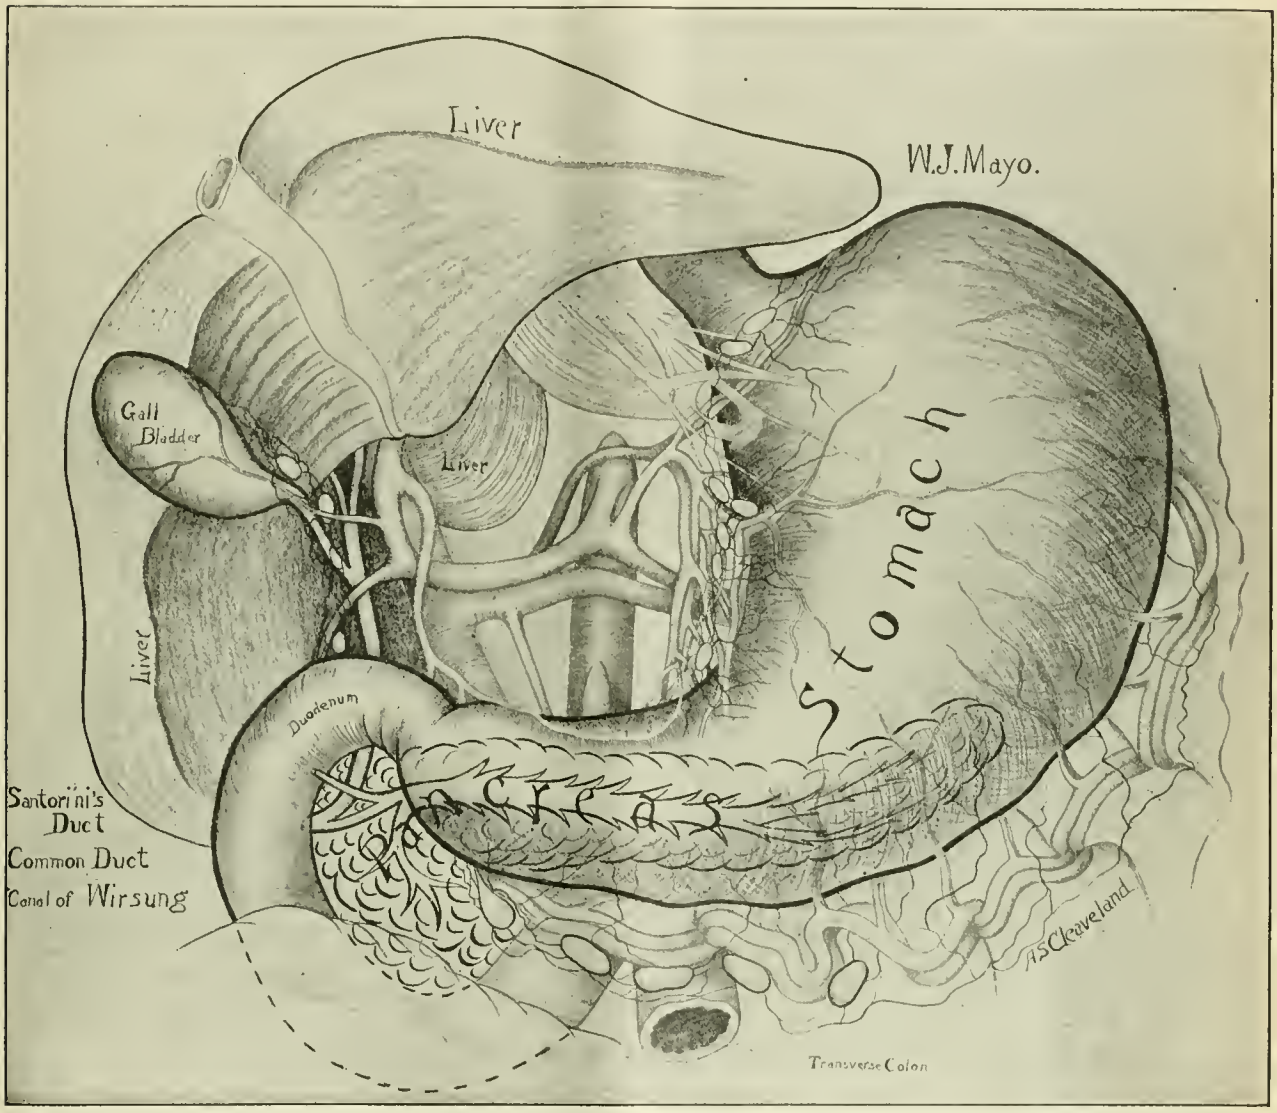
Certain parts of the body are so closely related in their anatomy, function and pathology as to be almost necessarily considered as part of the same system. The generative organs of women form so distinct a field of work as to have built up a specialty. Can we separate diseases of the kidney from the ureter, bladder and urethra? By no means. Each may stand in an etiologic relationship to the others which can not be ignored.

In the upper abdomen we have attempted to study the stomach independent of the associated organs, the liver and bile passages, the duodenum and pancreas. The result has been a confusion in diagnosis and treatment. The palm of a hand may cover a serious lesion of any one of these organs, and that, too, at the point of greatest liability; not only so, but any one of this group may start a pathological process which may extend to any one of the others, and with fully as great frequency as occurs under similar conditions in either the generative or urinary systems.

Note the disturbance of the stomach which occurs with gall-stone disease; the adhesions to the duodenum and the pancreatitis, an association direct as it is vital. Again, let me call attention to chronic ulcer of the stomach with adhesions to the pancreas, secondary ulcer of the duodenum adherent to the bile passages or gall-bladder. These are not fanciful pictures, but drawn from every-day work. I have no hesitation in saying that with an operative experience of over 1,400 cases of this description, mistakes in exact diagnosis are still common, and in many instances unavoidable. The history may be the only valuable diagnostic resource when the patient comes to us, and we all know how unreliable that may be. Given a history of painful attacks which have been very severe, but which have completely ceased, with tenderness on deep palpation in the epigastrium, and we may have disease of any one of these four organs, and not infrequently an association either direct or indirect of the pathologic process. If we clearly understand the possibilities of error, we are better prepared to meet complications or execute a change of front and operate on one organ when another procedure was planned. In the majority of cases a pathological diagnosis is possible, and one can say with certainty, "This is gall-stone disease," or "This is ulcer of the stomach"; but in a considerable minority a surgical diagnosis is the best that can be made. That is, we can say: "In this locality is a diseased process which requires operative treatment, the exact nature of which must be determined by incision." The patient does not come to us for the purpose of having a certain operation performed, but seeks relief from suffering and disability.

Let me call your attention for a few minutes to the anatomic diagram, showing the nearly vertical position of the stomach with the pylorus in the middle line of the body, and but little elevated above the lowest point of the gastric cavity. It is turned upward and to the right just enough to prevent the weight of the gastric contents bearing directly on the sphincter apparatus. The only portion of the duodenum in which we are interested is the four inches lying between the pylorus and the papilla of the common duct of the liver and pancreas. This may be called the vestibule of the small intestines. Its position subjects it internally to the perils of ulcer from the acid gastric juices which its thin

tunics but inadequately resist. Externally its function is often interfered with by adhesions to the gall-bladder and bile tract, secondary to gall-stone disease. This unoffending bit of intestine is so often offended against as to cause it to become the most frequently diseased portion of bowel of the same length. The remaining eight inches of the duodenum is protected by the alkaline secretions of the pancreas and liver. Its fixed position and peculiar horseshoe shape, with its delivery point nearly as high as its origin, enable it to mechanically slow the



ingested material during the mixing process for which its large caliber affords accommodation.

The anatomy of the bile tract is equally interesting, and especially the relations of the common liver duct to the pancreatic duct and the duodenum. There is continuity of mucous surface, each protecting itself from the secretions of the others by the mechanical washing effects of its own secretion, the joint discharge and a feeble sphincter apparatus preventing entrance of the duodenal contents.

The gall-bladder, as it furnished the initial lesion in more than one-half of the diseases of this group, is of great interest. Like the appendix, an obsolete organ of storage function and limited outlet, it gives rise to a variety of troubles, which we are only of late beginning to appreciate. It is an old aphorism that "Nature finds mischief for idle hands to do." The gall-bladder has a capacity of about an ounce, and as we find almost universally in organs of storage function, the neck is raised slightly above the lowest point to prevent the weight of contents resting directly against the outlet. The little pouch thus formed may be called the pelvis of the gall-bladder (Brewer). It is here that the obstructing stone is so frequently lodged in cystic impactions. Murphy observes that the fundus of all organs has but few lymphatics, while the region of the neck has an abundant supply; hence, even with septic contents, there is but a mild reaction when the pelvis is obstructed, as compared with the startling temperature curves of duct stones.

The pancreas composed of two originally separated parts, has in nearly half of the specimens which have been examined two patent ducts, that of Wirsung, which is the important one, uniting with the

common liver duct. The minor duct of Santorini, however, has a possibility of useful function in certain diseased processes, as pointed out by Opie. The pancreas was originally an intraperitoneal organ, becoming retroperitoneal by a later evolution (Huntington), and in this anatomic peculiarity Brewer believes lies one of the reasons for the diffusion of fat necrosis resulting from acute pancreatitis. Mikulicz has called attention to the fact that adhesions to the pancreas in gastric cancer gave a mortality of 73 per cent. in his resection cases. Robson also notes the pancreatic mischief occasioned by perforating gastric ulcer on the posterior wall.

The blood supply of this group of organs is almost entirely from a single source in the celiac axis. It has been experimentally developed that the severance of all connctions of the pancreas excepting its blood supply, does not check secretion if food is placed in the gastrointestinal tract. In the nerve supply from the pneumogastrics and sympathetic ganglion, we find the same direct relationship involved. If we study the function we see the same association. The stomach can be compared to a mill, the fundus the hopper, in which the food is macerated in a weak solution of pepsin and hydrochloric acid, and the muscular pyloric portion the grindstones in which the masses are broken up into a homogeneous whole. The entrance of food into the duodenum causes the outflow of biliary and pancreatic secretions, the absorption returning to the liver by way of the portal vein. This is so elementary that you wonder that I should refer to it, yet the causation of the common surgical lesions lies in perversion of these fundamental functions, and is just as simple. Mechanical injury of the pyloric portion and excessive acidity of the gastric secretions, under anemic conditions, give rise to ulcer and lie behind the precancerous lesions which Ochsner notes is found in the history of cancer of the stomach in the majority of cases. The acidity of the gastric secretions renders the contents of the stomach, when turned into the intestine, relatively sterile, but increases the liability of ulcer of the duodenum. The sterility of the upper intestinal tract is still further increased by intestinal absorption, as shown by Adami, the bacteria being picked up and destroyed in part by the glands. Many germs are, however, carried to the liver, and here either annihilated or screened out of the blood in the portal vein and discharged with the bile. We must look on the bile as always containing a few bacteria, and it is probably this attenuated infection of bile retained in the gall-bladder which gives rise to gall-stone disease, which in turn is the chief factor in the production of duct inflammation of both the liver and pancreas.

These considerations, so briefly outlined, taken in conjunction with the embryologic origin, justify the grouping of *the surgical lesions of the upper digestive tract*, and at once enable the diagnostician to associate the symptoms and the surgeon to direct his attention, not to one, but to the entire group of organs. The burden of proof lies with the practitioner, not only to demonstrate that the disease rests in one organ, but to differentiate and show that no other is involved.

The art of the diagnostician lies in the proper valuation of the signs and symptoms of disease in organs of associated function and pathology. The instinct which seems to lead some men to a correct conclusion, and by a mental process they could not themselves analyze, usually depends on few things, the immaterial or inconclusive evidence being unconsciously discarded. For instance, note the value of the colic in the diagnosis of gall-stones. The typical attack comes on and stops abruptly, is relieved by vomiting or a feeling of movement of gas, is irregular in time, in regard to food, and not accompanied by temperature or pulse elevation, and leaves the patient able to attend her duties almost immediately after cessation of pain. While the pain lasts, it is excruciating, felt in its greatest intensity in the epigastrium, radiating upward behind the sternum and into the back. The distress penetrates to the right side, but occasionally to the left, and lasts from a few minutes to six or eight hours. When the patient comes to the physician it may have been years since the typical attacks; he may have forgotten them, the present trouble complained of being pain, digestive disturbance, and tenderness on deep pressure over the gall-bladder region. The history of the early attack is worth more than the physical examination in many cases. Compare it with the pain in gastric or duodenal ulcer, which may be just as severe, but lasts a day or two longer, especially when due to regional peritonitis, and is accompanied by gastric symptoms and local tenderness. The patient diets, which means he reduces his food supply. The symptoms last more or less for some days or weeks, and the interval of apparent cure gives some weeks or months of comparative health.

Acute perforations of the organs of this group are relatively common and give rise to symptoms which would be at once recognized if they occurred in the region of the appendix, but occurring in the upper abdomen too often go to a fatal issue unoperated. The initial symptoms are remarkably alike, whether of the gall-bladder, the duodenum, stomach or acute perforation of the pancreas with fat necrosis. The onset is essentially the same in each. Sudden extreme epigastric pain, with collapse, ushers in the attack, and muscular rigidity, as a rule, comes on early. The diagnosis of perforation, if we are on our guard, is easy, although it may be difficult to say which organ is affected; but this does not make any difference. The vital consideration is that it has happened, and immediate operation must be performed.

In 811 operations on the gall-bladder and bile tract we had 4 acute perforations of the gall-bladder, with but one recovery, although the average mortality in the benign series was but 4.47 per cent. In 45 operations for duodenal ulcer, 4 acute perforations occurred, with 2 recoveries, while in the 41 operations for subacute and chronic ulcer there was only one death. In 469 operations on the stomach, 5 perforations occurred, with 2 deaths. In 32 operations for diseases of the pancreas, there was only one operation for acute pancreatitis and fat necrosis, with recovery. This gives 14 cases of acute perforation, with a mortality of 50 per cent., and why? Because the operation was usually too late. The death rate in over 1,150 operations for subacute and chronic benign conditions of this group of organs averaged a little less than 5 per cent., counting as a death from operation any patient dying in the hospital without regard to cause or time elapsed between the operation and the fatal issue. If we add to this mortality of 50 per cent. in operations for acute perforation, the cases seen in a moribund condition beyond even attempt at relief, and the still larger number in which death occurs without an ante-mortem diagnosis, we get some idea of the appalling nature of the disaster. To be successful, operation must be immediate; the condition is as

imperative as hemorrhage from an artery of the third class. Few recover operated on later than ten hours after perforation. The conditions simulating perforation in the upper abdomen, such as thrombosis of the mesenteric or splenic vessels, diaphragmatic and duodenal hernia with strangulation, and so forth, are rare, and likewise call for early operation.

As a rule the history and location of the early acute pain will furnish evidence as to the origin of the trouble. Preceding perforation of the gall-bladder there are often symptoms of several days' duration with a history of gall-stones. The acute pain occurs in the gall-bladder region. Early drainage with removal of the gall-bladder should give a mortality of not to exceed 10 per cent.

Duodenal perforation usually occurs in cases of chronic ulcer with years of symptoms preceding; but the immediate onset is exceedingly acute, and not ushered in by a few days or hours of prodromata, as is often the case with the gall-bladder. The location of the early pain is just to the right of the median line. The liquids gravitate at once to the appendiceal region and simulate perforated appendix. The rapid diffusion of escaping contents is fatal to delay. Operation for acute perforation of the duodenum is rarely successful after eight hours. Suture of the perforation with suprapubic pelvic drainage, and after-treatment in the sitting posture (exaggerated Fowler's) in early cases should give 80 per cent. or more of recoveries.

Gastric perforations occur on the anterior wall, according to Brunner, 7 times to 1 posterior, and near the cardiac end 5 times to 3 times in the pyloric portion, and near the lesser curvature 122 times to 16 times near the greater curvature. The initial pain is usually to the left of the median line, and early diffusion of fluids is to be expected. Only 10 per cent. occur without previous symptoms of chronic ulcer. The results of operation being in direct ratio to the amount of gastric contents, and the length of time which has elapsed, the treatment is similar to the duodenal ulcer.

The term perforation of the pancreas from inflammation with resulting fat necrosis is a purely pictorial expression, and not a pathologic entity in the sense the word is used in the preceding remarks, yet it conveys the ideal and calls attention to the value of peritoneal drainage in its treatment, as shown by Woolsey. The symptoms are sudden pain in the epigastrium, collapse and early extreme distention of the abdomen. On opening the peritoneal cavity, free fluid often of a hemorrhagic character is evacuated. The little fatty masses in every direction and the enlarged pancreas call attention to the source of the trouble. This particular phase of acute pancreatitis cannot be separated from the hemorrhagic type in which treatment is as yet in an unsettled state. Those interested in this question will find a mine of information in the Hunterian lectures for 1904 by Mayo Robson.

The group of acute perforations gives an unsatisfactory mortality, with a prolonged period of disability from drainage, and without a certainty of permanent cure of previous underlying conditions. This will not long continue. Like acute gangrenous appendicitis, the condition will be recognized early with corresponding improvement in results.

The diagnosis of the chronic infective lesions of the organs of this group is in a far more satisfactory condition. The general mortality of gall-stone operations is not above 5 per cent., taking the cases as they come, but even this is too high. Grouping the cases in which the entire process is limited to the gall-bladder, the mortality is from 1 to 2 per cent., and depends to a large extent on the general condition of the patient. Secondary complications, chiefly those which involve the hepatic and common ducts with resultant cholangitis, pancreatitis, and so forth, are responsible for the death rate. As practically all of the patients have symptoms on which a diagnosis could be based previous to the complications, it will not be long before early operation in patients otherwise in good health will be the rule as it is now in chronic and relapsing appendicitis. Not only is the mortality thereby reduced, but the disability is likewise lessened. The average stay in the hospital for uncomplicated gall-stone patients is slightly less than seventeen days; the convalescence of the complicated duct cases is prolonged one or two weeks.

Chronic infections of the pancreas are usually secondary to gall-stone disease, and, as a rule, do not occur excepting where the common duct has been directly irritated by the presence of calculi, although the consequences may continue for some time after the passage of the offending body. The results of drainage of the gall-bladder and bile ducts are extremely satisfactory. In our series of 32 cases there were but 2 deaths; these patients had coincident suppurative cholangitis.

Chronic infective lesions of the stomach with ulcer as a type are becoming better understood every day, as surgical operation discloses the actual conditions present. The primary mortality of operations for their relief are in a fairly satisfactory condition, but as to ultimate results we can not say definitely. For the obstructive complications the result of ulcer, there can be no question as to the relief afforded and at a nominal risk. The dilated stomach with retention or stagnation of food suggests at once drainage operations with gastrojejunostomy as the type. We have patients of this description alive and well more than twelve years after operation.

Chronic ulcer without mechanical obstruction gives a less promising outlook. The very fact that there is normal gastric motility indicates that gastroenterostomy or other drainage operation is less necessary. Our results in operations for this description of lesion have not been wholly satisfactory, and furnish a considerable percentage of secondary operations and failures to relieve.

Cannon's experiments have shown the same results. A gastroenterostomy on a normal stomach of an animal does not drain the gastric cavity, even if placed at the lowest point. The gravity advantage of the gastroenterostomy is overcome by intra-abdominal tension, and the food, by muscular action, is carried out the pylorus rather than the artificial opening. The magnificent showing of gastroenterostomy in obstruction has led to the indiscriminate performance of the operation in those cases of ulcer in which gastric drainage is normal. This particular phase of the subject must be further investigated.

Chronic ulcer of the duodenum is relatively more common in the upper two inches than in any corresponding portion of the stomach. It is especially liable to perforate, although its sheltered situation usually leads to adhesive protection. Many pyloric ulcers will be found to have their origin on the duodenal side. Gastroenterostomy is the operation of choice as it diverts the irritating gastric juices and food products from the sensitive surface, thus promoting rapid healing. We have performed gastrojejunostomy 286 times for all purposes, with a mor-

tality of 5½ per cent. in the benign series. The recent improvements in the technic of gastroenterostomy has greatly reduced the mortality and largely eliminated the causes of failure to mechanically relieve the conditions. Moynihan well says that "the surgeon may not unreasonably expect that from being a last resource gastroenterostomy may be considered as a method of treatment worthy of consideration in a much earlier stage of chronic ulcer of the stomach." Excision of gastric and duodenal ulcers would seem to be a wise procedure, but is open to certain strong objections. In 20 per cent. of cases more than one ulcer is present, and one or more may be undetected or lie in an inaccessible situation. It leaves the ulcer tendency unrelieved and more ulcers may form. Rodman has suggested the removal of the pyloric or ulcer-bearing portion of the stomach with complete closure of both duodenal and stomach ends and independent gastrojejunostomy. We have followed this plan in 5 cases of inveterate ulcer relapsing after gastroenterostomy, with good results. The gastroduodenostomy of Finney is a most excellent operation, and we would predict a wider field of usefulness than it has enjoyed. We have performed this operation 46 times, with one death, and no relapse. The theoretical objection is that in open ulcer the food must pass the ulcerated area before reaching the widened pylorus, and obstruction has no part in the production of ulcer, as is shown by the development of duodenal ulcers. Pyloroplasty must be discarded. While we had no death in 20 operations, we had 7 relapses.

In briefly calling attention to the malignant diseases of this group of organs, the writer would emphasize the possibilities of cure by means of operation. In the gall-bladder we found 4 per cent. of cases at the operating table had malignant disease, and all of these cases had gall-stones present or evidence that they had been present at one time.

Since it has become the practice to remove all thick-walled gall-bladders as useless and a possible source of future trouble, many cases of malignant disease in an early stage have been in this way, as one might say, accidentally cured. We have met with several such instances.

Cancer of the stomach is the most common type of malignant disease in the human body, constituting one-fourth to one-third of the total number. The radical treatment of gastric carcinoma is now on assured ground, with a mortality of 10 per cent., or less in favorable cases, to 20 per cent. in late but still operable disease. The only necessary thing for success is an early diagnosis, and this must be on clinical grounds, supplemented by early exploratory incision. In 46 gastric resections for pyloric cancer we had 7 deaths.

The profession may well look on the surgical achievements in this new field of work with pardonable pride. That there are many shortcomings must be admitted, but in the history of surgery there has never been a territory opened up with equal rapidity, nor one in which the physician and surgeon have worked together in such harmony for the common good. The statistics on which this paper is based represent the operative experience of Dr. Charles H. Mayo and myself.

Tent for Consumptives.—The Central Church, of Chicago, has devoted the collection of one Sunday to the providing of one home tent for consumptives at Whitehead, Col.

PROGNOSIS: ITS THEORY AND PRACTICE.[1] [2]

BY GEORGE DOCK, M.D.,

OF ANN ARBOR, MICH.

The topic I have ventured to bring before you is "Prognosis: Its Theory and Practice." As a text, let me quote from the oldest work we have on this subject,[3] which, though old, still has the freshness and modernism that genius gives to human productions:

"It appears to me [said the Father of Medicine] a most excellent thing for the physician to cultivate prognosis; for by foreseeing and foretelling, in the presence of the sick, the present, the past and the future, and explaining the omissions which patients have been guilty of, he will be the more readily believed to be acquainted with the circumstances of the sick; so that men will have confidence to entrust themselves to such a physician. And he will manage the cure best who has foreseen what is to happen from the present state of matters. For it is impossible to make all the sick well. This indeed would have been better than to be able to foretell what is going to happen; but since men die, some even before calling the physician, from the violence of the disease, and some die immediately after calling him, having lived perhaps only one day or a little longer, and before the physician could bring his art to counteract the disease; it therefore becomes necessary to know the nature of such affections, how far they are above the powers of the constitution. Thus a man will be the more esteemed to be a good physician, for he will be the better able to treat those aright who can be saved, from having long anticipated everything, and by seeing and announcing beforehand those who will live and those who will die, he will thus escape censure."

In this Hippocrates describes the essential importance of prognosis to the patient and the physician in relation to treatment. Besides this, prognosis is often important to relatives and dependents, not merely for reasons of sentiment, but in order to protect property and prevent unhappiness and destitution that would be as painful for the patient to contemplate as for the others to suffer. There is another aspect not present in the time of Hippocrates—giving the patient an opportunity to prepare himself for the anticipated life beyond the grave. In many cases, too, prognosis may have important bearings on political parties or for the commonwealth.

The patient very often ignores these needs. If he asks for anything, it is usually either the name of the disease or that of the medicine the physician intends to use. He really understands as little of the significance of the name as he does of the action of the drug, and is often more quickly satisfied in proportion as both answers are occult. What really should interest him is, as clearly as his mental development permits, some idea of the changes in his body, anatomic and functional, their present seriousness, the chances of death, or of complete or partial recovery, with, in the latter case, the probability or temporary or permanent disability, near or remote, in some organs or functions.

Within the last century prognosis has lost some of its relative importance. Unlike etiology, diagnosis, prophylaxis and treatment, it has no special literature, and is only occasionally the subject of addresses or essays. But much of the so-called prognosis of the earlier periods was really diagnosis, as in Hippocrates' vivid description of empyema, and his remarks in regard to other diseases of the respiratory organs. It also seems

[1] Abstract of Oration in Medicine at the Fifty-fifth Annual Session of the American Medical Association at Atlantic City, June 7 to 10, 1904.

[3] The Book of Prognostics; the genuine works of Hippocrates, Adams' translation, Vol. I.

a mistake to assume that practical prognosis was more accurate at any period than in later ages of equal enlightenment. While we may admit that great masters, like Hippocrates himself, Galen, Sydenham and Boerhaave, were remarkably accurate in their prognostications, there is no reason for thinking that the rank and file, following their rules without having their keenness of observation and precision of reasoning, were more accurate, or as accurate as physicians of a later period when the formal study of prognosis was neglected, but when other means of knowledge were greater than before. We must bear in mind a fundamental difference in methods. The older prognosis was based on the observation of symptoms alone, and consciously or unconsciously took the standpoint of humoral pathology or some equally imperfect theory. One charge against ancient prognosis is not as serious as some have thought, viz., that the prognosis was made without a definite diagnosis. Even now we sometimes have to be satisfied with a very imperfect diagnosis, and yet may make a very good prognosis, at least for the immediate future. But the older prognosis was almost wholly lacking in anatomic, and totally without chemical basis. Realizing how far short of accuracy the diagnosis must have been in many cases, we can understand that prognosis must have failed almost as often. Moreover, in early medicine, most attention was paid to acute diseases, or the acute terminations of chronic diseases, so that the many important chronic diseases that now make so much of medical practice were comparatively neglected.

Whatever shortcomings medicine may have—and those who cultivate the subject most thoroughly feel them most deeply—it must be admitted that diagnosis is much more certain than ever before. Not only are we able to distinguish more quickly and more accurately many diseases long known, such as some of the acute fevers, malarial disease, tuberculosis, diphtheria and pneumonia; but we have learned the existence and the means of detecting many diseases formerly confused with others. As examples, let me name only a few, such as the diseases originating in the vermiform appendix and the gall-bladder, diseases of the pancreas, many diseases of the blood, a large number of diseases of the nervous system and of the ductless glands, and many diseases caused by animal parasites, of which the sleeping sickness is the most striking example at present.

The older prognosis, far from being negligible, is really of fundamental importance. It gives the accumulated experience of ages that, untrammeled by detail, carefully noted broad and elementary features of disease. As gathered together in the aphorisms and prognostics of Hippocrates, and in the numerous commentaries on them—not always improving the original—it furnishes a fund of inestimable value, but like everything else in medical art, this knowledge is less useful when applied mechanically than when worked over in the crucible of personal experience, tested by other methods and transposed into current formulæ.

Older prognosis was possible to collect into fairly circumscribed space, but this is no longer true. In proportion as diagnosis has become subdivided, specialized and enlarged, and as knowledge of morbid processes has become more complex, so prognosis has become more intricate. Older prognosis was based on broad symptomatic lines, qualified in practice, we may be sure, by a consideration of the patient's constitution. The present basis is diagnosis, but of a different kind. It means not merely a recognition of the name of the disease, but a knowledge of the nature of the disease, still incomplete, but rapidly gaining in fullness and accuracy. In many cases we know the causes, and a good deal of the nature of the causes; in many more we know the seats of the disease, and the anatomic, chemical and functional changes that result directly and indirectly. It is by the study of the altered functions that we can make a prognosis and plan useful treatment without knowing the name of the disease. Clinical and anatomical investigations have been aided by experiments and observations on lower animals, without which our knowledge would have been much less certain than it is. Scores of technical methods have been devised for reactions and explorations; natural forces previously unknown, such as the X-rays, have quickly been pressed into service. Long and painstaking observations have thrown much light on complications and sequels, their nature and detection. From all these things the prognosis proceeds naturally in most cases, but here again an indispensable part is a just recognition of the patient's constitution. It is probably true that in this connection we unduly neglect some prognostic aids furnished by the patient, such as changes of the physiognomy. But, on the other hand, we have much more accurate methods of ascertaining the constitutional factor than were formerly available. Constitution is still a somewhat vague term, but we can speak of it here as the result of the functions of all the organs. While the method of representing these functions is still inadequate, we can safely assert that we have much more accurate means of determining the condition of the heart, arteries and veins, and the force of the circulation than we had before; we have gone considerably beyond the recognition of the apoplectic habit in foretelling the danger of vascular disease. We can usually estimate fairly well the efficiency of the blood-forming organs; we can determine with reasonable accuracy the capacity for work of the stomach and intestines, as well as a few details of nutrition and metabolism; we are rapidly getting beyond the limitations of Falstaff's water doctor in fixing the anatomic and functional ability of the kidneys, and we are working toward methods of testing the functions of liver, muscles and nerves. When we have all these factors thoroughly investigated it is probable there will be little need of the *vis medicatrix naturæ*, now an essential part of prognosis.

In the conclusion resulting from these things there is no room for a supposititious clairvoyance, an intangible gift of prophecy, a hypothetic intuition that trained intelligence can not equal or industry surpass. We have a positive knowledge, a prescience, a prognosis, corresponding in accuracy and usefulness to our diagnosis, and often in advance of our treatment.

In the foregoing I have spoken of the theory. In the practical use of prognosis the first to profit by that function is the physician. With an accurate prognosis, based on exact and thorough examinations, knowledge of the natural course of the disease and of the patient, the physician foresees the course of the malady and is prepared for changes, emergencies and complications. He is thus enabled not only to preserve his imperturbability, so essential in carrying out necessary measures of treatment, but he can also prepare the patient to meet coming events in better physical and mental condition than otherwise, and, what is often of even greater importance, the self-confidence thus shown stimulates the efforts and the compliance of others concerned in the case.

Physicians, like other people, can often be classified as either optimists or pessimists. Not that these tendencies affect all parts of the individual's activities. One may be a perfect Pangloss in sociologic, political or climatic matters, and yet take a gloomy view of all his patients. (I am not speaking of those who, rarer in the profession than in some of its parasitic growths, habitually exaggerate the danger of their cases, making every angina a diphtheria, every erythema an erysipelas and

every bronchitis a threatened pneumonia.) Another who is perpetually cast down by the failure of democratic government or the need of a stronger one, the immorality of the rich and the rule of the bosses, may meet every case with hope and cheer.

But the practice of prognosis should be cultivated as objectively as any other part of medicine. Not only the therapeutic indications suggested by it, but also the human ones, should be carried out without fear or timidity, without unnecessary harshness, but also without the false benevolence that often does more harm than brutal frankness or ignorance. Here, as in other departments of medicine, the welfare of the patient must be the touchstone by which the action proposed should be proved.

No disease should be looked on as insignificant. Nothing seems less becoming than to hear medical men speaking lightly of disease in general, or of any disease in particular. It is no consolation to the mother whose child has died of one of the rare complications of chicken-pox to find that many physicians think that too trivial to concern themselves with it. Nor does it increase confidence in the profession to have hysteria and neurasthenia considered imaginary and ridiculous evidences of perversity, while the impatience, not to say lack of scientific interest sometimes shown toward other less well-defined neuroses, undoubtedly has some relation with the crowded ranks of followers of isms of all kinds.

In acute diseases the best general rule is still that of Hippocrates (Prognostics; 19, Sect. II): "In acute disease it is not quite safe to prognosticate either death or recovery." A case of this kind, however, should not be considered likely to die unless from a complication, or from the effect of a pre-existing disease, though in certain diseases, such as scarlet fever and diphtheria, the danger of a sudden change and of death should be made known in the beginning. Of course, in cholera and plague, and even in cholera infantum, such information is rarely necessary. In some other acute diseases the study of prognosis prepares the physician not to be unduly elated by the remissions that are so reassuring to relatives. The temporary amelioration in meningitis and peritonitis, in which the patient seems almost free from symptoms, may be mentioned. Less disappointing, but still ominous, is the occasional lull in bronchopneumonia. But in the cases I have just mentioned it is rarely advisable to bring the unfavorable probabilities too strongly before the patient. In these we often need the effects of reassurance and of hope. For the latter as we see it in medical practice is not merely the "kind nurse of old age—hope—which," as Pindar says, "more than aught else steers the capricious will of mortal man," in acute cases especially it is distinctly stimulating to physical and mental processes. Sir Dyce Duckworth, speaking from a ripe experience, recently gave an address on "Hopefulness in Medicine," in which he emphasized this fact, and Niemeyer, equally successful in his career, at his medical promotion defended among others the thesis *medicus semper hilaris*. On the other hand, it is a serious error not to point out, after recovery from certain acute diseases, the possibility of sequels, sometimes months or years afterward, and the advantage of examinations at intervals for the purpose of detecting them before they become inveterate. The thorough examination of the urine at intervals after scarlet fever, of the lungs after pleurisy and all bronchitic diseases, of the heart and arteries after many infectious diseases, often has great practical value.

In chronic diseases there are few exceptions to the rule that the patient should be told the nature of his case as fully as possible. At least, in patients who can be made to understand, and who have a possibility of recovery, of definite improvement or of long duration, there are only individual exceptions. Patients with tuberculosis, heart disease, kidney disease, and disease of the alimentary tract can not get the best possible results unless they understand why and how they should do certain things and why they should avoid others. Tact and patience and a knowledge of human nature are essential in this. The statements made should be as simple as possible, as brief as definiteness permits, without pathological explanations. Better no statement than an unconsidered or an unintelligible one.

In talks of this kind we too often forget how different are the ideas of non-medical persons, even those who have studied physiology in the public schools, from our own, regarding the body, its functions and diseases. I am always interested in seeing how soon medical students lose the lay point of view, just as one forgets an unused foreign language, and how sometimes they never recover it. Yet unless they do, they lack valuable means of giving aid. Darwin has noticed how everyone who studies profoundly a subject often becomes unaware on what points the ignorant require information. Carlyle, as John Beattie Crozier tells us, imagined his stomach as some old teakettle, thickly encrusted with fur, and I have seen an otherwise intelligent man on the point of using strong sulphuric acid for a cough, because he found by experiment that oil of vitrol dissolved sputum more quickly than any other reagent he had tried. Nor is it enough to make the explanation. We must ascertain whether the statements are understood, and, if possible, whether they are accepted. How often, even with an intelligent individual, after we have stated the existence of a small tuberculous focus, and described the results of rational treatment, we find the patient shutting himself in a dark and close room, taking "lung cures," cough syrups and more or less medicated cod-liver oil, and how often, after demonstrating the sufficiency of dietetic treatment in a digestive disease, we find the patient taking bitters, digestive ferments, usually well neutralized by alcohol, antiseptics and other drugs less easy to classify. So time and patience must be devoted to this part of the work, and we should never be discouraged by failure. I am convinced that there is an improvement in the possibility of carrying out rational treatment, notwithstanding the insidious propaganda of useless or dangerous methods in and out of medical journals.

It is much easier to advise in cases that have a strong tendency to recovery than in those that have not, and there is room for difference of opinion and of practice in the latter, because the conditions vary with patients according to individuality and accidental factors. A number of aspects present themselves for consideration. In the first place, there is often an element of diagnostic or prognostic uncertainty, where the prospects are better than they seem. Sir Dyce Duckworth[1] has formulated universal experience in pointing out the advantages of the "cautious 'if,'" and if the alternative accepted is the hopeful one, much good can be accomplished in many cases. An interesting example is given by Kussmaul in his fascinating "Jugenderinnerungen." Having made a reputation as a zealous dissector, and having won over his confiding peasants to the many advantages of post-mortem examinations, he was asked by the father of a girl with advanced tuberculosis of the peritoneum to arrange for an autopsy on the daughter, when she died. Although Kussmaul, too, thought the daughter was lost, he retorted that he could not speak of an autopsy until the patient was dead. Notwith-

[1] Duckworth, Sir Dyce: Address on Medicine, British Medical Journal, 1896, II, p. 251.

standing many obstacles, the girl recovered. The tendency to take the less hopeful alternative is still shown in some cases of tuberculous disease in stages not far advanced, though it is not so common, fortunately, as it was not many years ago, to see such patients given over either to a life of dissipation or of abject despair. The prognosis of valvular disease of the heart is also in a much more optimistic vein than it was fifty or even twenty-five years ago. However, in many cases the prognosis needs to be tested by a therapeutic "if" that is not as well recognized as it deserves. The physical conditions may seem hopeless, and yet if the action of the heart can be improved the case may assume a very different aspect. The advantages of trying were well illustrated by a case in which a woman with aortic and mitral insufficiency and moderately severe loss of compensation was given up as beyond treatment by her family physician. Not knowing this I told the relatives the impossibility of complete recovery, the danger of sudden death or more probably rapid failure at any time, but also the possibility of improvement and a fairly comfortable life for some time, all the more worthy trying to realize, because the condition was not complicated by medicinal action, and the other important organs showed no serious alteration. The family physician then wrote me admitting that he had stated improvement was out of the question, and treatment not worth trying, although under subsequent treatment the patient lived two years and nine months.

In cases hopeless in a more certain degree than such as I have just mentioned, it too often happens that treatment is abandoned too early in the case. Patients with cancer of the stomach or other inoperable tumors, cirrhosis of the liver, and many other diseases are permitted to drag out their existence without relief.

There are several reasons for this. Sometimes families having been told the truth about such a patient, refuse all further medical aid, even when the conscientious physician who gives the information points out what can still be done.

Many physicians voluntarily discontinue attendance when they realize that the end is inevitable, with the feeling, doubtless, expressed by Sir William Temple. The latter said that "an honest physician is excused for leaving his patient when he finds the disease growing desperate, and can, by his attendance, expect only to receive his fees, without any hopes or appearance of deserving them." This, however, ignores the fact that in such cases the accomplished physician can often do more real good to the patient than in many cases that recover, while the opportunities for obviating despair, alleviating pain and soothing mental anguish, and for exhibiting thoughtfulness, gentleness, persistence and variety of resources, are more valuable to the physician than any fee. Even in acute cases it sometimes happens that the physician is either discharged or withdraws because the indications seem hopeless, and I have known of patients with pneumonia living for one or two days in this way, the family waiting for the end of a life that with greater effort might have been saved. Sir Francis Bacon described this tendency as one of the deficiencies of medicine, "so that Sylla and the triumvirs never proscribed so many men to die as physicians do." For, as he continued, "the office of a physician is not only to restore health, but to mitigate pain, and not only when such mitigation may conduce to recovery, but when it may serve to make a fair and easy passage."

Improvement in methods of treatment have an important relation to prognosis, in that many diseases considered hopeless at one stage of knowledge, may in another offer many chances for recovery or alleviation. In this connection a critical knowledge of current medical literature is necessary, and a realization of the value of medical evidence. Few things can be more disastrous to the physician's mental development—never completed—than constant change of therapeutic method, but there are differences. One need not try every drug proposed for the treatment of typhoid fever or pneumonia, nor every new antipyretic or hypnotic. But the physician who does not inform himself quickly of the value of surgical treatment in various disease as it is developed, in pelvic diseases, brain diseases, diseases of the appendix, biliary tract, stomach and pancreas, comes very near deserving the reputation of an unscrupulous practitioner. In these departments, too, mistakes are made and exaggerations are inevitable concomitants of progress, but the gain is often distinct and unmistakable, and often changes the prognosis from one extreme to the other.

The rule in regard to giving the patient a good prognosis and the relatives a bad one, can often be followed, but is a very fallacious one on the whole. It is often more necessary to keep up the spirits of the relatives, especially those who have to nurse, than those of the patient, so that sometimes the rule can be reversed with advantage. Darwin cites some interesting and instructive examples of this kind, from his father's practice, and Bilroth has expressed himself with much feeling in one of his letters. Moreover, the relatives informed, either from a feeling of compassion or otherwise, may not bring the patient to act on the information, and I have known of serious financial loss befalling a family because the relative entrusted with the task of breaking the news to the patient did not do this. Another risk is that the relatives may divulge the fatal prognosis in such a way as to put the physician in the light of a heartless deceiver, and thereby cause the patient to lose all confidence in him. On the whole, in cases where the patient should know the truth the physician is often the best one to state it, and he should see that this is done before it is too late.

Exceptions to the rule of candor may occur in the case of children, in women with no spiritual obligations or business responsibility, or in exceptional cases in men. No general rule can be laid down, but that such exceptions occur can be confirmed probably by every physician.

Of course, this part of the subject is closely related to the theory of ethics, and many writers on this subject have touched directly on the question of medical veracity with, as one might anticipate, diametric differences of opinion. Some moralists of the strict school of Kant and Fichte insist that any deviation from the absolute truth is wrong in medicine, as they assert that it would be wrong even for the purpose of saving the whole race. Others believe with Paulssen, who says: "There is not a physician in the world who does not give deceptive answers to his patients, who does not excite hopes that he does not share. He does not blame himself, nor do others, for everyone does the same." Johnson, "the stern old moralist," in his remarks on the subject, laid open a serious flaw in his own logic: "You have no business with consequences, you are to tell the truth." But surely the physician's chief interest is with the consequences, and if he thinks the patient can gain only by misrepresentation, it is just as proper for him to use it as it would be to give a medicine that in other cases might be quite improper. But the physician in such a dilemma would do well to bear in mind the next sentence in Johnson's *ipse dixit:* "You are not sure what effect your telling him that he is in danger may have. It may bring his distemper to a crisis, and that may cure him." Jonathan Dymond, as strict as any one in his morality, threw a gleam of stern humor into the

discussion: "Persons frequently employ falsehoods to the sick man who cannot recover, lest it should discompose his mind. This is called kindness, though an earnest preparation for death may be at stake on their speaking the truth. There is a peculiar inconsistence sometimes exhibited on such occasions. The persons who will not discompose a sick man for his interest in futurity, will discompose him without scruple if he has not made his will."

This part of the discussion might be indefinitely prolonged, but I think we can never get far away from the principle. I intimated in the beginning—that in practical prognosis we must individualize, just as we have to in therapeutics, with the patient's welfare ever the object of our activity.

Accidents that follow an unfavorable prognosis occasionally suggest a revision of methods. I have already alluded to the error formerly not uncommon in the treatment of tuberculous patients. More acute results sometimes follow a fatal prognosis, as in two of my patients who resorted to suicide. One was a man with far-advanced carcinoma of the stomach, to whom I recommended palliative treatment and advised against a useless effort at radical treatment. The patient left for his home, but threw himself from a fast train and was killed. In another patient, a man with a large kidney tumor, apparently with many adhesions, my surgical colleague and I advised against an operation. The patient went to another hospital, and apparently received similar advice, for he shot himself through the tumor, and died in a short time. From a broad biologic standpoint it does not, of course, make any difference whether an individual organism dies as either one of these, or as it would if left to its fate. But no matter how one may feel on the subject of suicide, I have always thought these men less fortunate than another patient with carcinoma of the stomach, also far advanced. To him, in advising against an operation, I added that if he could find a good surgeon who was willing to operate, he might submit. He underwent the operation at the hands of one of the most distinguished surgeons in the country, and died on the table. In such a case the result is often unfortunate, because it prevents operations on other and more promising cases, but for the man himself, fighting to the last, it seems to me one can have only respect.

This brings up a question on which a few words may be proper—the question of euthanasia. Every few months some one—usually not a physician—proposes that people with incurable diseases should be killed by some painless method. The plan offers so many opportunities for crime that it would be difficult to carry out, but aside from that it involves important principles. The difficulty of telling when the proper time had come would often be insuperable. Aside from examples of fortitude and other virtues exhibited by the dying, how much the world would have lost if a chronic invalid like Stevenson had the cord of his life snapped at one of the times when the *aes triplex* of his soul seemed battered through! To take a less selfish view, we can think of the "picture of human patience, the visions of ripened character, which have been revelations and inspirations to generations of mankind" (Phillips Brooks), and see these repeated daily in sick rooms of all degrees, while the self-sacrifice and kindness developed in others at such times cannot but be of untold benefit to the race. To most physicians the suggestion of any planned shortening of life must be abhorrent. For countless generations they have been doing their utmost to lengthen life and lessen disease. They have shown how to prevent the plagues that formerly made life almost as bad as a perpetual illness for the survivors, and they have also shown how many deaths can still be prevented. On the other hand, they can, in most cases, so treat the dying man that the bitter anguish often associated with death is absent, that life is not only less painful, but actually longer, so that they will continue to follow the rule of the Father of Medicine, and "give no deadly medicine to any one, even if asked, nor suggest any such counsel."

PREVENTIVE MEDICINE: ITS ACHIEVEMENTS, SCOPE AND POSSIBILITIES.[1][2]

BY HERMANN M. BIGGS, M.D.,

OF NEW YORK;

GENERAL MEDICAL OFFICER, NEW YORK CITY DEPARTMENT OF HEALTH; PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE AND ADJUNCT PROFESSOR OF MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

The terms sanitary science, public or state medicine, and preventive medicine, have frequently been used as almost synonymous. The latter term, "preventive medicine," however, has sometimes been restricted in its application to the prevention of the infectious diseases. In the broad sense, preventive medicine comprises both general prophylaxis and individual prophylaxis, and applies to all forms of disease, not simply to the infectious diseases. Preventive medicine is an applied science, which deals with the preservation of the health both of the individual and of the community.

No subject more vitally concerns the welfare of a community than that pertaining to its healthfulness. How the inhabitants live and how and at what age they die, what is the extent and character of the morbidity occurring among them and what are its causes, are questions of momentous importance. They are essential features in the problem, whose solution will teach men how they may live longer, healthier, and therefore happier lives.

In rural districts the average healthfulness of the inhabitants depends largely on natural conditions, such as elevation, climate, soil, and, to a much less extent, on the artificial conditions produced by the handwork of man. In densely populated cities, on the contrary, the natural conditions become relatively unimportant features in determining the degree of healthfulness, so much do they become subordinated in many cases to the artificial conditions which have resulted from the lives, labor and occupations of the inhabitants. It may be said with certain limitations that the inhabitants of any city in the temperate zone now have it largely within their power to determine what degree of healthfulness their city shall have. A high morbidity and a high mortality in any urban population depend largely on some remediable features of an unsanitary character, such as the sewerage of the city, the occupations, habitations, food and water supplies, and the habits of the inhabitants—all factors which lie to a great extent within their control. Hence, when any city in modern times has a high annual death rate, for example, 30 to 35 per 1,000, as was formerly the case in New York, Liverpool and other cities, instead of a death rate of 17 to 18 or 19 per 1,000, as now exists in London, Berlin and New York, it is because conditions are permitted to exist partly from the neglect, indifference and ignorance of the people, and partly from the lack of proper facilities and necessary efficiency on the part of the authorities.

The expectation of life at birth in certain manufacturing cities of England has been but little more than

[1] Abstract of an Address on State Medicine at the Fifty-fifth Annual Session of the American Medical Association at Atlantic City, June 7 to 10, 1904.

one-half that of the healthiest districts of England. Until recent years it was twenty-five or twenty-six years in Liverpool and Manchester, thirty-seven years in London and forty-six years in Surrey, a healthy country district. Even at the age of thirty years, the expectation of life was seven years more for England as a whole than it was for the inhabitants of Manchester. I have estimated that the expectation of life at birth in New York City in 1866 was only a little more than twenty-five years, while in 1903, calculated on the death rate for that year, it had almost doubled, and equaled about forty-two years. For the seven-year period ending in 1873 the death rate under five years in New York City was 123 per 1,000 of the population at these ages. For the year 1903 the death rate under five years was 56. On the present estimated population at these ages, this reduction equals a saving of more than 28,000 lives annually.

In the seventeenth and eighteenth centuries the average annual death rate throughout the civilized world was at least 50 per 1,000 of the population, and probably it was much more than this. From 1628 to 1635 in London, these years being free from pestilence, the average death rate was 50 per 1,000, and the absolute annual mortality for twenty-four years, from 1620 to 1643, was over 70 per 1,000. The death rate during 1902 in London was only 17 and a fraction per 1,000. The mean expectation of life in London for the decennial period, 1771-1780, as calculated by Price's table, was 19.6 years, the annual mortality being 51 or 52 per 1,000; while from 1831 to 1835, although an epidemic year is included, the death rate had decreased to about 32 per 1,000. In 1894 the mean expectation of life at birth for all England had more than doubled that of 1780 in London, so that it was nearly forty-one years, and for London alone it was thirty-seven years. From 1771 to 1780 in London not less than five in each thousand of the population died annually of smallpox; in 1810 this mortality had sunk to two per 1,000, and in 1835 to 0.8, and in recent years it has been an absolutely insignificant decimal. Fever as a cause of death declined in almost the same ratio, from 6.21 in the decennial period ending in 1780 to 2.64 in 1810, and 1.14 in 1835. In the sixteenth century fever, plague, cholera and dysentery destroyed annually 31 out of every thousand of the population of London, or nearly twice the total deaths occurring now from all causes. These diseases at the present time, as causes of death, do not equal in London 2 per 1,000 annually of the population.

In old New York City (comprising the boroughs of Manhattan and the Bronx), for the seven-year period ending in 1873, 616 out of every thousand children born died during the first five years of life. As computed by the death rate under five in 1903, 280 would have died during these same five years. This mortality, while still far too high, equals a reduction of nearly 60 per cent., and as calculated for the estimated population at these ages, means a saving of about 20,000 lives a year in these boroughs. The death rate in the period over five years of age has naturally shown a much smaller decrease, although it has fallen from 19 or 20; as it was in 1865 and 1866, at the time of the organization of the Department of Health of New York City as at present constituted, to about 14 for the year 1903, being a reduction of nearly one-third. This has been accomplished notwithstanding the fact that the old city has increased during this time from a population of about 750,000 to more than 2,200,000.

It does not seem necessary or desirable for our present purpose to consider in detail the causes of this decrease or the special diseases in which it has taken place, but the facts suffice to indicate the great achievements of preventive medicine during the past four decades.

The scope of the sanitary measures in force with reference to the ordinary infectious diseases has in recent years been greatly broadened. More than ten years ago the Board of Health in New York assumed the position that all facilities and procedures looking to the prevention and cure of the infectious diseases should be afforded by the Department of Health. The establishment of the methods for bacteriological diagnosis and the facilities for the serum treatment had their origin there, and have since been widely followed.

General prophylaxis, or that portion of preventive medicine which should come directly under the supervision of the health authorities, has or should have, a broader scope than that indicated, and should include the supervision, not only of those diseases which have generally come within sanitary surveillance, but also all the infectious diseases which from their nature are to a greater or less extent preventable, in addition to all other forms of disease which are the result of unsanitary living, occupations, habitations or surroundings, including those diseases arising from manufacturing, mining, or other industries which, on account of their nature, are peculiarly or especially injurious to health. It should also include with greatly increased powers and breadth of jurisdiction, the surveillance of the water and food supplies and the sewage disposal.

There has long existed a belief in the medical profession, and to a considerable extent it has also been a part of the conception of the sanitary authorities of their functions, that the registration of a case of any kind of infectious disease involved some surveillance of such case by the authorities. The slightest consideration would at once show that with relation to many of the diseases mentioned no such surveillance could be of any real service, and it might be a source of annoyance to the sick person, the family and the attending physician. Much good, however, would result, in my opinion, by such a broadening of the scope of sanitary work, without causing annoyance or being detrimental to any one. I should like, however, to point out that more than a year ago the Board of Health of New York City in the revision of its sanitary code included a number of new sections in relation to the infectious diseases, covering to a large extent the diseases above mentioned. These sections, with the accompanying notes, read as follows:

INFECTIOUS DISEASES.

SEC. 133. It shall be the duty of every physician to report to the Department of Health, in writing, the full name, age and address of every person suffering from any one of the infectious diseases included in the list appended, with the name of the disease, within twenty-four hours of the time when the case is first seen:

A. *Contagious* (very readily communicable): Measles, rubella (Rötheln), scarlet fever, variola (smallpox), varicella (chicken-pox), typhus fever, relapsing fever.

B. *Communicable:* Diphtheria (croup), typhoid fever, Asiatic cholera, tuberculosis (of any organ), plague, tetanus, anthrax, glanders, epidemic cerebro-spinal meningitis, leprosy, infectious diseases of the eye (trachoma, suppurative conjunctivitis), puerperal septicemia, erysipelas, whooping cough.

C. *Indirectly Communicable* (through an intermediary host): Yellow fever, malarial fever.

SEC. 134. It shall be the duty of the commissioners or managers, or the principal, superintendent or physician, of each and every public institution or dispensary in this city, to report to the Department of Health, in

writing, the full name, age and address of any person suffering from any one of the infectious diseases included in the list appended, with the name of the disease, within twenty-four hours of the time when the case is first seen:

A. *Communicable:* Influenza, lobar pneumonia, bronchopneumonia, infectious diseases of the gastro-intestinal canal (dysentery, cholera morbus, cholera infantum, summer diarrheas of infants).

B. *Parasitic Diseases of the Skin:* Scabies, *Tinea tonsurans,* impetigo (contagious), favus.

It will be noted, first, that two main groups of diseases are specified. In the first group, including the more readily communicable diseases, and some others which are not so regarded, registration is compulsory in all cases coming under the observation either of a private attending physician or an institution. These are separated for convenience under three heads: (*a*) The contagious or very readily communicable; (*b*) the communicable, including diphtheria, typhoid fever, Asiatic cholera, tuberculosis, and a number of others, and (*c*) the indirectly communicable, including only two diseases —yellow fever and malarial fever—which are transmitted solely through an intermediary host. In these three classes compulsory registration is required because in all of the diseases in these classes preventive measures, properly executed, are certainly efficient to a very large extent. As to the propriety of the compulsory registration of all of the diseases included under the first heading, "The contagious or very readily communicable diseases," I assume that there can be no reasonable difference of opinion. Measles, Rötheln, scarlet fever, varicella, variola, typhus fever and relapsing fever, certainly without question, should be reported to the sanitary authorities. The necessity for reporting Rötheln and varicella rests more in the danger of confusion of these diseases with measles and varioloid, respectively, than because of the importance of the diseases themselves. Our experience in New York has shown again and again that outbreaks of smallpox have resulted from the failure of inexperienced physicians to recognize mild cases, these having been mistaken for varicella and treated as such. Every case of varicella occurring in the city must, therefore, be reported, and all cases occurring in adults are immediately seen by a trained diagnostician. I say all cases of varicella in adults, because experience has shown that very frequently varicella in an adult is a mild case of variola.

In the second class, called simply "the communicable diseases," there might be some question as to the propriety of the reports in some instances. There would be none, however, with regard to diphtheria, typhoid fever, Asiatic cholera, plague, tetanus, anthrax, glanders and leprosy.

There can not now be, nor can I conceive that there ever will be again, any serious question as to the necessity or propriety for the registration and sanitary surveillance of tuberculosis, although this has been a subject of very bitter dispute and although this disease has come actually under the close supervision of the sanitary authorities in only three or four cities in the United States, and of practically none in Great Britain or on the Continent. Pulmonary tuberculosis was included in the list of communicable and reportable diseases by the New York City Board of Health ten years ago, and the measures adopted for its surveillance have been gradually extended and the lines for its restriction have been drawn closer and closer as each year has passed. Some doubt, however, might properly arise as to the necessity of the inclusion of other forms of tuberculosis than pulmonary tuberculosis in the registration returns, because for the most part these other tubercular diseases are not communicable, or very slightly so.

The infectious diseases of the eye—trachoma and suppurative conjunctivitis—should be included because of the importance of the adoption of preventive measures in the public schools. Few persons had any conception of the great prevalence of these diseases of the eye in the public schools of New York until after the Department of Health adopted some comprehensive measures for their surveillance. Such a vast number of cases was found that the Board of Health was forced to establish special dispensaries and provide special hospital facilities for their care. Only within a few weeks a second hospital and dispensary has been opened, and in the original one in connection with Gouverneur Hospital an average of about 500 patients a day were treated during the year 1903, and nearly 5,000 cases were operated on for trachoma.

Puerperal septicemia should be included in the registration returns because modern aseptic midwifery has shown that in most instances this is a strictly preventable disease, and excepting rare cases of difficult or prolonged labor, its occurrence may be regarded as the result of uncleanliness, negligence or incompetence.

No one, I fancy, would seriously question the propriety of including erysipelas and whooping cough in the registration returns. So far as this country is concerned I assume that typhus fever, Asiatic cholera, plague, leprosy and yellow fever are diseases which will never again call for anything more than occasional or emergency measures for the disposal of isolated cases or small groups of cases.

The registration of cases of malarial fever should be required, not because close surveillance of individual cases is necessary, but because the sanitary authorities should know where the sites of infection are, where the breeding places of the *Anopheles* mosquitoes are to be found, in order that they may adopt proper means for determining the cause of such areas of infection and the proper measures for their removal. In certain sections of New York City investigation has shown that in some instances almost every person living within certain small areas has suffered from malarial fever during the spring and summer months of a single season. Such outbreaks are without any question the result of local remediable unsanitary conditions, which furnish the breeding places for the mosquitoes. But without special information as to the existence of the cases, only to be obtained through the registration of malarial fever, knowledge of the presence of such unsanitary conditions and their removal, may become difficult or impossible. The surveillance in their homes of the individual cases reported is of course not contemplated. That conditions similar to those found in New York exist in other communities, I have no doubt.

Section 134 of the Sanitary Code of New York, covering the second group, deals with infectious diseases of a somewhat different type, and in these the Sanitary Code requires the reporting to the department by public institutions of all cases coming under their observation; but it only requests physicians to report them and does not require such reporting.

Class (*a*) in this group includes some of the more important acute infectious diseases of the upper respiratory tract, namely, influenza, lobar pneumonia and bronchopneumonia, and certain of the more common acute infectious diseases of the gastro-intestinal canal, namely, dysentery, cholera morbus, cholera infantum and the summer diarrheas of infants.

The acute diseases of the respiratory tract referred to should, in my opinion, be registered, because they are

infectious, because they are of prime importance as causes of death, and in order that general and special investigation may be instituted for the collection of data bearing on the modes of infection and the sources and causes of their prevalence and their distribution. New York City has during the last winter experienced the greatest prevalence of these diseases which it has had for many years. In the first four months of the year more than 6,000 deaths occurred from influenza, lobar pneumonia, bronchopneumonia and acute bronchitis.

Investigations in New York and other localities have shown that serious outbreaks of diarrhea and dysentery have occurred in various institutions and in local areas which were probably, if not certainly, preventable, but concerning which the sanitary authorities have had no information. It seems evident, therefore, that these diseases should be made notifiable.

Notification of the parasitic diseases of the skin should be required chiefly because of the liability to the extension of these diseases among children in the public schools.

There are certain very large and important questions of prophylaxis connected with the prevalence of typhoid fever and the milk and water supply of our large communities. The occurrence of great outbreaks of typhoid fever, such as the epidemics at Ithaca, N. Y., and Butler, Pa., during the last year, the prevalence in Philadelphia, Pittsburg and some other cities of the United States and the extensive distribution in the rural districts, constitute a disgrace to American preventive medicine and should arouse the sanitary authorities, the medical profession and the people to the provision of efficient measures and the enactment of suitable legislation for its prevention.

The annual cost of typhoid fever in sickness and death throughout the United States would be computed in terms of tens of millions of dollars. All of this loss we know is certainly preventable. If only a small portion of the annual outlay made by the country for sickness and death from this cause were expended in the education of the people as to the cause and the methods of prevention of this disease and the provision of proper water and sewerage systems, typhoid fever might soon become a rare affection. Unfortunately the city sanitary authorities are often almost powerless in this matter, as their jurisdiction does not extend over the watersheds which supply with water the people under their care, and a supervision by them of the sources of the milk supply is also frequently absolutely impossible.

In New York City detailed investigations of all the cases of typhoid fever occurring within the city limits were instituted several years ago and have been continuously carried on. These show that at least 25 per cent. of the cases occurring in the city have *certainly* received their infection outside of New York City, and a considerable percentage more have *probably* received it outside. Five or six per cent. are the result of contact with other cases, and the remainder are in all probability almost wholly the result of infection through milk or oysters.

A serious objection which may be urged against the adoption of the measures here recommended in regard to the registration of many infectious diseases is the increased labor thrown on physicians which their enforcement would involve. The question may properly be asked: Whether the sanitary authorities in the interest of the general public may call on the medical profession for the expenditure of so much time and labor without making any compensation in return. There are 35 diseases included in the New York list. The English authorities pay a fee for the notification of each case of infectious disease, and I believe that this course might properly be pursued in this country; but this has not been the custom here, and the authorities generally are not now provided with the funds necessary for this purpose.

When the Department of Health of New York City established its bacteriological laboratories in 1892, measures were adopted to make some return to physicians for their interest and labor in connection with the sanitary surveillance of the infectious diseases. A systematic plan was then inaugurated, and has since been consistently followed, to secure their cooperation, by offering free bacteriological examination in the diagnosis and surveillance of various forms of infectious disease. This was first applied to Asiatic cholera in 1892, during the outbreak in New York harbor, and has since been extended to all of the diseases in which existing scientific knowledge made it possible, cerebrospinal meningitis being the latest disease added to this list. The establishment of this system of free bacteriological examinations in the diagnosis and surveillance of the infectious diseases, and the provision of facilities throughout the city for the collection of specimens and the sending of reports to physicians, constituted an entirely new departure in sanitary work and has been of the greatest value. The example of New York has been followed by the sanitary authorities in most of the large cities of this country, by many state authorities, and by authorities generally, in Great Britain and to a certain extent on the Continent. These examinations constitute the return which the authorities here have made to physicians for the reporting of cases and for their assistance and cooperation in their care. This return has a very considerable money value, when we remember that for such examinations the usual fee is $5, and as physicians cannot, as a rule, make such examinations themselves, they must work without the assistance thus afforded, unless they appeal to the regularly constituted laboratories.

What now are the possibilities of preventive medicine as concerns the larger centers of population? In answering this question we may first take as the basis of our reply the conditions found in some of the large cities with the lowest death rates, or still better, the conditions found in some healthy rural districts. In considering the crude death rates, as ordinarily reported, however, one must not ignore the influence of the sex and age distribution of the population on the death rate. As is well known, the death rates in the period of life between five and forty-five years of age are very low, and the death rate among women is lower than among men. If, then, in a city there is a relative excess of the population in the middle periods of life, or an unusual preponderance of women, we may have a crude death rate which seems very low, but which when corrected may be relatively high. For example, the death rate of New York City, as corrected by the English life tables, would probably be at least three points higher than it is. For 1894 the gross rate was 22.76, and the rate corrected by the English tables was 26.46. The corrected death rate of some of the large, rapidly growing Western cities would probably be five or six points higher than the crude death rate reported. The death rate of London at present averages about 17 per 1,000, and when corrected about 18.5 per 1,000, while the Berlin death rate is somewhat lower than this. The crude death rate of Surrey, a healthy rural district in England, is 14 and a fraction, and when corrected would probably be 15.

We can hardly use for a basis of comparison the conditions in any of the cities of this country with very low rates, because the rates have not been corrected, and the basis on which they are calculated cannot always be accepted as correct. Taking all the facts together, and judging of the duration of human life as we know it, we

may accept a corrected death rate of 14 or 15 in a large city as a goal toward which preventive medicine should strive and hope to achieve. If we consider the question from another point of view, as to what is possible in the reduction of the death rate from distinctly preventable diseases, we would reach a conclusion not unlike the previous one.

In New York City it may be assumed that the present tuberculous death rate of 2.7 may, under proper surveillance, with certainty be reduced to 1.2, and 1.5 points would thus be subtracted from the crude rate. The diphtheria death rate, already reduced 65 per cent. by the use of antitoxic serum, should certainly be reduced to one-third of what it is at present; it is now about .6 per 1,000 population. Similar reductions should be possible in the death rate from typhoid fever, measles and scarlet fever. The diarrheal diseases of infants have already been reduced in the last twelve years to one-half of their former prevalence, and should still be reduced more than 50 per cent. Thus more than three points may be subtracted from the crude rate in New York, which in 1903 was 18.18. The rate would then be 15+. The rate for 1903 was the lowest in the history of the city.

The most fatal affections with which we have now to deal in New York are the acute respiratory diseases, including influenza, lobar pneumonia, bronchopneumonia and acute bronchitis. The average death from this group of diseases now exceeds three per 1,000 of the population, and in years when there is an epidemic prevalence of these diseases the death rate may be four or more, as seems likely to be the case this year.

The advances in preventive medicine have as yet not only had no influence in reducing the death rate from this group of diseases, but, on the contrary, there has been a slow and continuous increase. I cannot at this moment point out the method or the means by which a reduction is to be brought about, but still I firmly believe that with fuller knowledge such a reduction will become possible in the great cities where these diseases are so prevalent.

Something can be accomplished through the closer sanitary surveillance of the occupations and conditions under which the lower classes work, especially the noxious trades. Something, too, may be done through a closer supervision of foods to ensure their purity and freedom from adulteration.

A very difficult problem arises in connection with the diseases of the circulatory apparatus and the kidneys. My investigations have shown that in New York City a large increase has taken place, due to these causes, during the last twenty years. The acute respiratory diseases, cancer and diseases of the circulatory apparatus and the kidneys are the only important causes of death which have shown an increase during this period. The increase in cancer amounts to about 15 per cent., and the increase in the acute respiratory diseases amounts to about 15 per cent., while the increase in the diseases of the circulatory apparatus and kidneys combined equals about 40 per cent. In making this statement I have taken fully into consideration the possible influence of greater accuracy in the death returns, *i.e.*, the inclusion formerly of these under other causes of death; but after making all allowances, it seems to me without question that an increase equaling 40 per cent. has taken place.

Yellow Fever in Mexico.—Meridia reports to the Superior Board of Health of Mexico five cases of yellow fever, and announces increased sanitary activity to prevent the spread of the disease. A yellow fever patient was found in the street in Tehuantepec and properly cared for.

ORIGINAL ARTICLE.

PATHOLOGY AND TREATMENT OF SIMPLE FRACTURE OF THE PATELLA.

BY ELLSWORTH ELIOT, JR., M.D.,
OF NEW YORK.

A large amount of attention during the past ten or fifteen years has been devoted to the consideration of the clinical features of simple fracture of the patella. Prior to that time, and, consequently, before the introduction of aseptic methods, this lesion was usually treated conservatively, although in many instances the final result proved unsatisfactory, for not only was the range of movement in the affected knee-joint permanently restricted, but in addition its capacity to support the weight of the overlying body was greatly diminished. With the introduction of aseptic surgery, it was believed that much more satisfactory results could be obtained by the exposure and suture of the fragments, a procedure which afforded an excellent opportunity for acquiring a more accurate knowledge than had hitherto existed of the extent and nature of the damage to the bone and capsule. This procedure, in the early stages of its development was occasionally complicated by septic arthritis, and a stiff joint, or the loss of the affected extremity, or even of the life of the patient, was the unfortunate and distressing result.

With the perfection of aseptic technic, however, this risk of infection has been greatly diminished, although with justice it cannot be said to have been completely eliminated, but the disastrous results of infection are rarely seen. Notwithstanding this fact, however, the operation, although it has many enthusiastic adherents, still suffers the unmerited antagonism of the ultraconservative. These condemn any radical procedure on account of the risk of infection, no matter how remote the possibility of that complication and continue to advise conservative treatment, while admitting that operative interference usually provides a much more satisfactory result in a shorter time.

The less satisfactory result in cases treated conservatively, namely that of a stronger or weaker fibrous union, is ascribed by different observers to the presence of one or more of the following conditions: The paucity of the blood-supply of the fragments, their separation resulting from the effusion in the joint and from the contraction of the quadriceps, their occasional tilting on either a vertical or horizontal axis or on both, the interposition of blood-clot or of torn portions of the capsule or periosteum, and the difficulty of retention after approximation has been satisfactorily accomplished. From the difficulty of ascertaining the exact nature of the cause which, if not remedied, contributes chiefly to the development of fibrous union, as well as from the difficulty of recognizing the presence of an actual rotation of the lower fragment so extreme as to place its fractured surface parallel

to the overlying skin, it is impossible for the surgeon to accurately foretell the character of the ultimate result in cases where conservative treatment is adopted. While, in some cases, the union is sufficiently strong to permit ultimately of a return to a laborious or athletic occupation, the weakness of the extremity in many others permanently precludes such a means of livelihood—certainly a serious out-look for a very large fraction of the community. On the other hand, in case of operation and in the absence of infection, every assurance of complete and prompt restoration of the strength of the knee can be given to the patient and an extremity can be promised which will be sufficiently strong to permit of the patient's engaging in any laboring occupation which he may select.

The fact that the most advantageous form of treatment still occupies debatable territory seems to warrant the report of cases in which the operation of suture has been performed, as well as a statement of the lessons which they may have taught:

Case I.—J. M., male, twenty-eight years old; admitted to the Presbyterian Hospital, January 13, 1901. Patient was kicked by a horse on the left knee. He fell to the ground and could not rise. On examination there are the signs of a transverse fracture of the patella at the junction of its lower and middle third, the fragments being separated about 1¾ of an inch. There was moderate distention of the joint. Operation one week later. Gas and ether; usual procedure. The line of fracture extended laterally through the external part of the capsule for a distance of an inch. Suture. The joint was closed without drainage.

Case II.—L. G., male, forty-five years old; admitted to the hospital January 21, 1902; patient slipped on the ice and fell. He was unable to rise or to extend the knee. Examination reveals a transverse fracture through the middle of the patella, the fragments being separated by a distance of an inch. There was great distention, the circumference of the affected joint exceeding that of the normal side by three inches. At the end of ten days through the application of ice, massage and elastic bandages, this had decreased two inches. Operation, gas and ether; usual incision and exposure. There was a bilateral rent in the capsule on either side of the line of fracture, more extensive on the right side. Suture with drainage for forty-eight hours through a counter-opening on the right side.

Case III.—W. J., male, thirty-five years old; admitted to the hospital June 18, 1902. Eleven years ago, patient fractured the right patella. Good fibrous union was secured and an excellent functional result obtained by immobilization with plaster and straps. To-day, while lifting a heavy case, patient felt the right knee give way and he fell to the ground. On examination there is a transverse fracture just below the middle of the patella, the fragments being one-half an inch apart. Moderate effusion. One week later, operation; gas and ether. The capsule is torn on either side of the patella for a distance of about one inch. Closure without drainage.

Case IV.—C. O., male, forty-five years old; admitted to the Presbyterian Hospital November 3, 1902. To-day patient was thrown down, the right knee striking the sidewalk at a point just below the apex of the patella. There was loss of function. Examination shows a transverse fracture of the right patella at the junction of its upper three-fourths with its lower fourth. There is moderate effusion with a distance of three-quarters of an inch between the fragments. Operation four days later; gas and ether. The capsule was found torn for a distance of an inch from the inner extremity of the fracture. There was a rotation of the lower fragment on its horizontal axis through an arc of 90°, so that its fractured surface was parallel to the overlying skin. This malposition was corrected without difficulty.

Case V.—Male, fifty-five years old; admitted to the hospital January 12, 1903. One week ago, patient slipped and fell, sustaining a fracture of the right patella through indirect violence. On examination, there is a transverse fracture just below the center of the bone. There is moderate distention of the knee-joint. The fragments are about one-quarter of an inch apart. Operation two days after admission; gas and ether. On exposure the lower fragment is found to have become rotated on its horizontal axis through an arc of 90°, so that its fractured surface is directed toward the skin. On palpation, prior to the operation, the presence of this abnormal position was not suspected, the fractured surface not feeling unlike the normal anterior surface of the bone. At the time of operation this smooth feel of the fractured surface was found to be due to the obliteration of its irregularities by a thick layer of clotted blood. In this case the line of fracture was irregular and each fragment was still further bisected by a vertical fissure extending about midway between its lateral margins. No difficulty was experienced in restoring the position of the lower fragment and after suture the wound was closed without drainage.

Case VI.—P. T., male, thirty-eight years old; admitted to the Presbyterian Hospital January 25, 1903. During the past two weeks, the patient has received repeated trauma over the region of the right knee. There was no loss of function until one week ago when patient fell again. Examination reveals extensive swelling of the joint with a transverse fracture just below the center of the patella. There is a distance of about one-half an inch between the fragments. Operation five days later; gas and ether. The joint was found greatly distended with clotted blood. The upper fragment was bisected by a vertical fissure. The line of fracture was continuous with a bilateral rent in the capsule more extensive on the inner side. A counter opening was made on both sides for drainage.

Case VII.—P. B., male, forty-five years old;

admitted to the Presbyterian Hospital March 25, 1903. On day before admission patient fell down a flight of steps. There was immediate loss of function of the left leg. Examination revealed a greatly distended left knee and a transverse fracture of the patella at the junction of the upper and middle third. The fragments are about half an inch apart. Operation two days later; gas and ether. The joint was found to be greatly distended with blood clot. There was a small bilateral tear in the capsule opposite the line of fracture. An unusual amount of oozing seemed to warrant drainage, through a counter-opening on either side.

Case VIII.—J. H. S., male, twenty years old; admitted to the Presbyterian Hospital April 15, 1903. Six days ago, while attempting to reach some object on a high shelf by jumping, patient felt something give way in the right knee. There was immediate disability. On examination, there is moderate swelling both in the joint and the overlying soft parts. There is a transverse fracture at the junction of the lower and middle third of the patella separated by an interval of about one-half an inch. Operation two days after admission. A slight tear extending outward from the line of fracture was found in the capsule. A counter opening was made below and external for drainage.

Case IX.—C. B., male, thirty-five years old; admitted to the Gouverneur Hospital June 5, 1903. On day of admission patient fell from a truck, striking the left knee against the sidewalk. On attempting to arise, patient was unable to walk. Examination reveals a fracture at the junction of the middle and lower thirds of the left patella. There was moderate joint distention. Operation two days after admission; gas and ether. There was some inversion of the capsule between the fragments. Wound closed without drainage.

Case X.—L. G., male, thirty-nine years old; admitted to the Gouverneur Hospital May 15, 1903. On day of admission while attempting to push a hand-truck up an elevator shaft, patient lost his footing and slipped, feeling something give way in the right knee. On attempting to arise was unable to walk. On examination there is a fracture transverse at the junction of the lower and middle thirds of the right patella. There is moderate joint distention. The fragments are separated by three-quarters of an inch. Operation two days after admission; gas and ether. The capsule was torn especially on the inner side. Drainage through a counter opening on the inner side of the joint.

Case XI.—M. K., male, thirty-five years old; admitted to the Presbyterian Hospital November 30, 1903. This morning while going down stairs, the patient slipped, the right foot doubling beneath him. There was immediate loss of function and sharp pain in the vicinity of the left knee-joint. On examination there is moderate distention of the left knee-joint. There are the physical signs of a transverse fracture of the patella at the junction of its middle and lower third. There is an interval of three-eighths of an inch between the fragments. Operation two days after admission; gas and ether. The fragments were exposed by the usual incision. The knee-joint and the contiguous soft parts contained a considerable amount of clotted blood. The inner portion of the capsule was torn for a distance of an inch extending laterally from the line of fracture. The fragments of the patella and the torn capsule were sutured with chromic gut. Closure without drainage.

Case XII.—J. J. M., male, eighteen years old; admitted to the Presbyterian Hospital, January 4, 1904. This afternoon while exercising in the gymnasium, patient fell from a horizontal bar striking heavily on the left knee. Immediate loss of function and patient was conscious of the fracture taking place. On examination there is a transverse fracture of the left patella, at the junction of its middle and lower third; there being an interval of an inch between the fragments. There is extreme distention of the knee-joint and considerable discoloration of the overlying skin. Local application of cold with a posterior splint for one week with only slight diminution in the degree of distention. Operation; gas and ether. Usual incision, with the opening of the joint; a large amount of clotted and fluid blood escaped in a jet. There was rotation of the lower fragment on a horizontal axis through an arc of 90 degrees, the fractured surface looking directly forward. There was a bilateral rent in the capsule, extending from either extremity of the line of fracture, more extensive on the left side. The abnormal position of the lower fragment was easily corrected, and after thorough irrigation of the joint, the fragments and the torn capsule were united with chromic gut sutures, a small rubber tissue drain being introduced through a counter opening just in front of the external lateral ligament. Usual dressing.

Case XIII.—J. F., male, twenty-three years old; admitted to the Presbyterian Hospital January 20, 1904. This afternoon, patient was kicked by a horse on the right knee, falling to the ground. On being assisted to his feet, patient found that walking was impossible. On examination the right patella was found to be transversely fractured just below its center. The fragments were separated three-quarters of an inch. There was considerable swelling of the joint and overlying soft parts. Operation two days later; gas and ether. Through the usual incision the fragments were exposed and the joint opened; considerable clotted blood escaping from the severed soft parts and the joint cavity. There was a rent in the capsule extending from the outer extremity of the line of fracture transversely for a distance of an inch. There was no rotation of either fragment. After irrigation, the fragments and torn capsule were sutured with chromic gut and the skin closed, without drainage.

Postoperative.—In every case, primary union was secured and there was complete restoration

of joint function, both in the arc of flexion and extension and in joint strength as a whole.

Pathological Features.—Although, in all the cases, here reported, the line of fracture has been essentially transverse, the point at which it has passed through the patella has varied materially, being usually nearer the lower extremity or apex than the upper part of the bone. This variation is probably explained by the fact that the line of fracture must represent the mean between the force of the contraction of the quadriceps muscle and the resistance of the ligament patellæ being influenced as well by the angle of flexion at the time the fracture occurred, factors which necessarily vary in different cases.

The transverse line of fracture is not infrequently supplemented by a vertical one bisecting one or both fragments, a condition frequently recognized only at the time of operation for the reason that the fragments so formed are usually held in close apposition by untorn periosteum. In cases of this character, the result of muscular contraction, the vertical line of fracture must be due to the sudden and forcible action of the lower portions of the vasti insertions in either lateral margin of the bone. If present, such a condition may easily diminish the strength of the ultimate union of the fragments.

In simple transverse fracture, the fragments are usually separated by an interval of from between one-half and three-quarters of an inch, the interval always filled in with coagulated blood, which is firmly adherent to the roughened fractured surfaces and is continuous with a similar clot permeating the overlying aponeurotic layers and partially or completely filling the articular cavity. In no case here reported has interposition of periosteum been observed; on the contrary, the periosteum has not even been detached from the fractured margins. Occasionally, however, a torn portion of the adjacent capsule has been observed to lie between the fragments.

In the majority of cases, there has been a more or less extensive tear of the capsule; occasionally unilateral, generally asymmetrically bilateral, it has always been directly continuous with the line of fracture, and has penetrated the synovial investment of the joint. This "fracture" of the capsular ligament presents, frequently ragged edges, which must be removed to secure proper apposition. Failure to observe this precaution may lead to ultimate weakness of extension. The degree of damage to the capsule can only be determined, and its proper repair accomplished through an exploratory incision.

In three cases (Nos. 4, 5, and 12) the lower fragment has been found rotated on its transverse axis through an arc of 90 degrees, so that its fractured surface was in apposition with the subcutaneous fat. One might very naturally infer that the diagnosis of this malposition could have been made prior to the exposure of the fragment through direct palpation of its roughened fractured surface; such recognition proved impossible, however, because in each instance its irregularity was found to have been effaced by clotted blood. It is scarcely necessary to add that such a malposition, even if capable of recognition, could be corrected only through an open incision and that in the absence of such correction any conservative plan of treatment can only achieve failure.

Successful results obtained by conservative methods seem therefore to be a matter of good fortune, depending more upon the possibility of satisfactory approximation and retention of the fragments and upon the absence of tears in the capsule than upon the ability of the surgeon to recognize and rectify many of the conditions which interfere with proper union, and it is probably this very fact that accounts for the wide variability in the character of the result in cases which present similar physical signs and which are treated by the same conservative method; in those where satisfactory results are achieved, there has been no interposition of torn capsule, no tear or only very slight tears in the capsule and no rotation of the lower fragment, whereas poor results are the direct consequence of the persistence of one or more of these conditions, Nor is it possible to determine the presence of a rent in the capsule by the nature of the injury. To be sure, in fracture, the result of overmuscular action, the capsule is usually torn, while in those due to direct trauma, the damage inflicted may be limited to the bone. But both conditions are so frequently combined and the patient's statements so unreliable, because of the unexpectedness of the accident that accurate analysis of the cause may prove impossible.

The general plan of treatment which has been carried out in the cases here reported may be considered under three different heads:

1. Prior to operation.—The patient is kept quiet in bed and local applications of heat or cold made to the affected joint, which is placed on a posterior splint. These measures are continued until the local heat and tenderness subside and if possible, until some decrease in the degree of joint swelling has taken place. This usually requires from two to ten days, according to the extent of damage to the capsule and the amount of extravasated blood in and about the joint. If, at the end of that interval, there has been no decrease in the joint swelling, operation should no longer be delayed.

2. Operation.—The fragments of the patella and the torn capsule are most satisfactorily exposed by a curved incision joining with its convexity downward corresponding points between the patella and either tuberosity of the femur. The flap, thus formed, composed of skin and subcutaneous tissue is then reflected upward beyond the line of fracture.

After cessation of hemorrhage, all old extravasated blood is thoroughly removed; that beneath the skin and between the fascial layers preferably with a Volkmann spoon. The same instrument may be used for the removal of the blood between the fragments as well as for the

freshening of their surfaces. The clotted blood in the joint is most easily removed by irrigation and sponging. For this purpose a warm sterile salt solution or ordinary warm water that has been boiled proves least irritating to the synovial membrane.

The periosteum is then reflected backward a sufficient distance from the edge of either fragment to permit of the application of the drill which is passed obliquely so as to penetrate the fractured surface just in front of the posterior articular cartilage. Two such canals are made in corresponding parts of each fragment, heavy chromic catgut being used for the subsequent approximation.

The joint is once more thoroughly cleansed by irrigation, followed by the approximation of the fragments and the sutures of the tear in the capsule, the latter also with chromic gut. Throughout the entire procedure, the danger of infection is materially lessened if the removal of the blood, the irrigation and the subsequent sponging and drying are accomplished without the introduction of the finger of the operator or of any assistant into the joint cavity.

The question of drainage depends upon the amount of oozing that persists after the final irrigation. If this is slight no drainage is necessary; if excessive, a lateral opening is made on one side or both sides of the joint just anterior to the lateral ligament and a very small drain of rubber tissue inserted. This is invariably removed at the end of the forty-eighth hour and not replaced.

The deep fascia, the skin and subcutaneous tissue are now sutured with chromic gut. After the application of a sterile dressing, the limb is immobilized by a plaster splint reaching from the groin above to the malleoli below.

As a substitute for the drilling and suture of the fragments, the suture may be inserted through the overlying periosteum only. There is no question but that by this method, which requires less time, as accurate apposition of the bony fragments can be secured as by the suture of the fragments themselves, and also that, in the majority of cases no subsequent separation of the fragments occurs. The writer has always felt, however, that additional security is afforded by the suture of the bony fragments as well as of the overlying periosteum, and that in particular, the restoration of energetic active motion could be more quickly and safely accomplished.

Postoperative Course.—There is usually considerable pain, most severe directly after the operation and gradually diminishing until at from the fifth to the seventh day, it has completely disappeared. The temperature varies between 101° and 103° F., reaching normal about the tenth day. The degree of temperature as well as the length of its persistence, although in part due to the reparative process in the divided tissues, seems to depend chiefly upon the amount of extravasated blood. The writer has repeatedly observed as high a temperature as 103° F. in cases of hemarthrosis of the knee without the presence of fracture or wound, the temperature decreasing as the blood was absorbed. The pulse rarely exceeds 100, ranging usually between 80 and 90. A return to the normal rate is more quickly reached than is the case with the temperature.

Postoperative Treatment.—At the end of forty-eight hours, the drain, if any has been inserted, is removed and not replaced, a fenestra being cut in the splint for that purpose. In the absence of a drain, a change of the dressing is necessary only to make the patient more comfortable, the more or less completely desiccated compresses being replaced at the end of the third or fourth day. At the end of the tenth day, the sutured patella is moved gently from side to side, to prevent the formation of adhesions between its articular cartilage and that of the trochlear of the femur. At the end of the third week, the splint is removed, and the quadriceps daily massaged. At the same time, a moderate amount of passive flexion of the knee is practised. At the end of the fourth week, active flexion is allowed and the patient begins to bear some weight on the affected extremity and to walk. At the end of the fifth week, the patient is encouraged to go up and down stairs and as soon as possible thereafter to return to his regular occupation. During this period, there has been a gradual improvement in the degree of active flexion of the knee, and at the end of two months the patient should be able to bend the knee, to at least a right angle. In from four to six months, normal flexion may persist. No atrophy of the quadriceps muscle has been observed.

In all cases of fracture of the patella in which this operation has been performed, there is a permanent increase in the size of the bone affecting chiefly its transverse, and to a less extent, its antero posterior and vertical diameters. Such an increase has not affected unfavorably the integrity of the femur-patella joint, the formation of possible adhesions being prevented in each case by early lateral passive movement of the sutured fragments, as described in the after-treatment.

A careful consideration of the cases here reported, seem to warrant the following conclusions:

1. That, owing to the not infrequent uncontrollable rotation of the lower fragment, through an arc of 90 degrees on its horizontal axis, accurate apposition of the fractured surfaces cannot always be secured and under these circumstances the ultimate result of conservative treatment could scarcely prove satisfactory.

2. That suitable apposition may also be prevented by the interposition of torn shreds of capsule, by extravasated blood clot and possibly also by the interposition of untorn periosteum, conditions which can be recognized and remedied only by exploration.

3. That suture of the fragments permits of simultaneous suture of the torn capsule, a pro-

cedure of the greatest importance for restoration of joint security.

4. That the results of suture are almost invariably excellent, and that the risk of operation is comparatively slight.

5. Finally, that in no way does the writer desire to belittle the risk of operation. On the contrary, the exercise of the most rigid aseptic precautions both in the preparations for and in the carrying out of the operation itself cannot be too greatly emphasized. Far better, in any instance, where for any reason, the highest degree of surgical asepsis cannot be practised, to advise some non-operative procedure than to subject the patient to the possibility of a septic arthritis with all its direful consequences.

MEDICAL PROGRESS.

NEUROLOGY AND PSYCHIATRY.

Alcohol a Cause of Locomotor Ataxia.—It is generally considered that syphilis is the main cause of tabes, yet tabes is a very rare disease among women, though syphilis is not uncommon. Erb's statistics gave 19 cases of tabes among women to 350 in men; Fournier found the proportion one to 26, while Mendel found it one to four. Fournier also found that 95 per cent. of tabetics were syphilitic, while Berger found only 20 per cent. and Remak 23 per cent. Yet syphilitic lesions, even those of the central nervous system, are comparatively easy to cure, while tabes is practically incurable. PAPADOPOULOS (Le Progrès Médical, March 5, 1904) has practised twenty years in Asia Minor where syphilitics among women as well as among men, are particularly common, and where, because of inefficient treatment at the outset, tertiary lesions are usual and of the marked type rarely seen in Europe. And yet locomotor ataxia is practically unknown among women, and exceedingly rare among men. There is a great difference in the social life of the Orient from that of Paris and London. Alcoholism is rare, everybody drinks water. Practically the only liquors to be had are wine, raki and brandy, and these are taken only on special occasions. Wine is prohibited by the Mohammedans, though raki and brandy are allowed, the Christians of Asia Minor are teetotalers, not even drinking wine, and among the Mussulmans alcoholic drinks are not used. So, it may be accepted that syphilis, even in its worst manifestations, is common in Asia Minor, while the taking of alcohol in large quantities is quite rare. At the same time locomotor ataxia is very rare. So it is difficult to believe that locomotor ataxia owes its origin to syphilis, while one may be readily led to believe that alcohol is an important factor in the production of tabes.

New Sign of Basilar Meningitis.—The early diagnosis of meningitis in children is often very difficult and usually only one or two of the many possible signs may be present. G. W. SQUIRES (Med. Rec., March 26, 1904) has found that a sign, not heretofore described, has been invariably present in his cases, frequently as early as the fourth or fifth day. It is a rhythmical dilatation and contraction of the pupil and is elicited in the following way: The child's head is placed between the knees of the physician face upward with the body of the child supported on the bed or table. Gradual and forcible extension of the head upon the spinal column is then made. As the head is extended the pupils will be seen to dilate and the more extreme the extension the more marked the dilatation. Upon flexion the pupils contract so that when the chin is forcibly brought to the manubrium the pupils are well closed up. This can be repeated several times during the minute and each time the pupillary phenomenon will appear.

Prognosis in Epilepsy.—Almost all sorts of indications have been sought for in efforts to determine some ground for prognosis in this disease. WILLIAM A. TURNER (Lancet, April 9, 1904) concludes from a study of 161 cases, that the mental features of the interparoxysmal state should be divided into four classes. The first contains those epileptics without any obvious mental impairment, the fourth, those having the highest grade of dementia. Sex has little influence upon the mental condition, but it may be stated in general terms that males are numerically more afflicted than females, 91 to 78 per cent., but that the highest degree of dementia is somewhat more common in women than in men. A family predisposition to epilepsy and insanity favors the supervention of a certain degree of mental impairment. The duration of the disease influences the mental condition to some extent. Mental activity and mental deficiency are, however, observed in cases in which the disease has lasted respectively for over twenty years and for less than five. The age at the onset of the convulsions has some influence upon the subsequent mental conditions, and the earlier the onset the less probable the persistence of a clear mind. The character of the attacks have an important relation to the mental condition, the profoundest degrees of dementia being most commonly seen when the major and minor attacks coexist. When grand mal occurs alone, mental health is as common as mental deficiency. There is a direct association between the frequency of the fits and the mental state. Fits recurring in series are accompanied by a high grade of dementia. The term "facies epileptica" is found more commonly in the higher grades of dementia, but it is occasionally observed in patients whose memory alone has been impaired. Of the 161 cases used in the preparation of this paper, the intellectually normal represented 13.6 per cent.; those with impaired memory, 31.6 per cent.; feeble minded, 25.4 per cent.; demented 29.1 per cent.

The Movements of the Superior Intercostals in Hemiplegics.—The symptomatology of the brain, particularly that which subserves localization outside of the motor areas is in an evolutionary stage. It is still quite unsatisfactory. The uncertainties of cortical and subcortical lesions are based upon a very crude physiology outside of a few simple principles. In this connection the clinical study of L. P. CLARK, on the movements of the superior intercostals muscles in hemiplegics is of interest (Am. Jour. Med. Sciences, December, 1903). The work consists of a review and confirmation of the observations of Hughlings Jackson, which were first published by him in 1895. This principle was to the effect that during quiet respiration in hemiplegics there is overaction of the superior intercostals on the paralyzed side, while during forced respiration the reverse results—the sound side overacts. In Jackson's original 28 cases he reported the presence of this symptom in 18. Clark has examined 161 cases and found it present in all lesions of the brain where the integrity of the capsular fibers was destroyed. In all the symptom was to be detected by inspection or palpation. The importance of such a symptom is obvious. The author unfortunately has not given a careful analysis of the cases, especially regarding the degree and extent of brain lesion. Granting the constancy of the symptom in destructive lesions of the capsule we have yet to determine the precise cortical elements which

are so grossly affected in the extensive capsular disease. From Clark's supposed pathology and the experimental work of Spencer, the cortical accelerator and arrest respiratory centers quoted by him (Lancet, Dec. 16, 1899) one is interested to know whether definite focal lesions in these brain areas by tumor or abscess will give this symptom. It should certainly be looked for. If present, it may rank with astereognosis in focalizing value. Even if respiratory arrest and acceleration are functions presided over by relatively large brain areas, which seems to be the case for the stereognostic instinct the former may still broadly prove of focalizing value. To settle the latter point, further careful experimental and clinicopathological work is necessary.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Agglutination of Tubercle Bacilli in Animals.—The blood-serum of healthy rabbits never agglutinates tubercle bacilli but if rabbits are experimentally infected, the test is positive in only one-half of the animals, according to E. Schwarzkopf (Münch. med. Woch., April 12, 1904). The agglutination is most frequent about three weeks after infection and gradually decreases as the tubercles surround themselves with connective tissue. This corresponds with the clinical experience that the phenomenon is more common with tuberculous patients in the first stage than with those in the third. Animals near death also failed to react. Animals infected with strongly virulent bacilli of bovine tuberculosis agglutinated less frequent than where less virulent germs of human origin were employed. Positive results were occasionally obtained where no pathological lesions were found. It seems very improbable from these experiments that the test will ever be of much diagnostic value in man.

Crystals in Icteric Feces.—In the stools of icteric patients a large number of needle-shaped crystals are often found, whose composition is not known, since insoluble in all the ordinary media. By means of a special process, T. Kimura (Münch. med. Woch., April 12, 1904) was able to isolate them in a pure condition. The ash contained much calcium and a little sodium and magnesium, which was held in combination with stearic and polmitic acid in the form of insoluble soap.

Precipitin Reaction in Mummies.—An interesting observation is recorded by J. Meyer (Münch. med. Woch., April 12, 1904), showing that the precipitin reaction is absolutely specific for human blood, no matter what the source or age of this blood. The musculature of several mummies, one of them five thousand years old, was extracted and then tested in the usual way. A precipitate was only obtained when the serum of rabbits treated with human serum was added; when the serum of other animals was added, the fluid remained permanently clear, just like with fresh material.

Improvement in Widal Test.—It is often impossible for the practising physician to perform the Widal test, since he lacks the bacteriological apparatus to grow typhoid germs. Recently a permanent culture of bacilli treated with formalin has been recommended, and D. Ehrsam (Münch. med. Woch., April 12, 1904) has tried this in a large number of cases and has obtained equally as reliable results as with fresh cultures. In all cases of typhoid agglutination was obtained in three to twenty-four hours, while in all other febrile disorders the test was negative.

Ferments in the Urine.—Every urine contains proteolytic ferment, and J. Grober (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 5 and 6) points out that this is generally pepsin, while during the absorption of pathological infiltrates and exudates, and in diabetes mellitus, trypsin is occasionally found. By determining the critical temperature the author could prove that gastric and urinary pepsin are identical bodies; furthermore, if the stomach in animals is extirpated no more pepsin will be excreted. During fasting the amount is considerably higher than normally. It is probable that the excess of ferment is absorbed by the blood as zymogen and is again converted into pepsin, where it encounters an acid reaction, as in the kidneys.

Cryoscopy for Exudates.—L. v. Ketly and A. v. Torday (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 5 and 6) believe that cryoscopy is of some value in determining if a collection of fluid will be absorbed spontaneously or not. Thus, in chronic pleural exudates, absorption can be looked for where the lowering of the freezing point is close to or less than that of the blood-serum. This, however, applies only to those cases where there is no fever or other sign of pleural inflammation, since here an increase of effusion can be expected. In case of hydrothorax secondary to nephritis, the freezing point of the serum must also be determined and the figures are only of value if renal function is satisfactory. The rules for pleural fluids also hold for those depending on tuberculous peritonitis. In other peritoneal transudates, cryoscopic examination is in place only where there is no mechanical obstruction and the heart's action must always be taken into account before giving a decision. It is often hard to distinguish between exudates and transudates since the specific gravity and amount of albumin may vary within wide limits in both. The authors had hoped that cryoscopy might be of some help, but numerous experiments conducted in this direction were without result.

Pathology of Pneumobacillus Pneumonia.—There seems to be little doubt at the present day that the Friedländer bacillus is able to set up a typical pneumonia like the pneumococcus. Certain well-marked differences in the pathology of both infections are pointed out by I. Kokawa (Deutsch. Arch. f. klin. Med., Vol. 80, Nos. 1 and 2). The diseased portions of the lung are generally much increased in volume; they may involve an entire lobe or form multiple foci throughout one lobe. The cut section appears granular, rarely smooth and is characterized by an extreme slippery sensation to touch owing to the presence of a large amount of mucus, especially in the early stages. This is not, however, pathognomonic, for it also occurs in the later stages of diplococcus pneumonia. Histologically there are changes in the alveolar epithelium in the form of swelling, proliferation, desquamation and necrosis of the cells, and migration of red and white cells into the alveoli. In the stage of red hepatization, the hemorrhage is not as marked as in pneumococcus pneumonia, while during gray hepatization the fibrin formation is less pronounced. The emigrated leucocytes appear larger owing to the presence of vacuoles; they, together with the epithelial cells, form the most abundant constituents of the exudate during the later stages. The behavior of the bacilli in the diseased tissue is rather typical. They are taken up by the epithelial cells and leucocytes, which swell up and develop vacuoles in their interior. These vacuoles are derived from the mucoid capsule of the germs and always contain one or more germs. The pleura and bronchi show the same lesions as other forms of pneumonia. A number of other infections may be caused by the capsule bacillus, thus pleuritis, pericarditis, endocarditis, otitis media, abscesses, phlegmons and osteomyelitis are occasionally reported. The meninges seem to be affected equally as often as with pneumococci. The fact that a pneumonia could be set up in three guinea-pigs by injecting cultures of the Friedländer bacillus, seems to speak for the specific character of the germ.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JUNE 11, 1904.

THE AMERICAN MEDICAL ASSOCIATION.

THE fifty-fifth annual session of the American Medical Association at Atlantic City, which was held on Tuesday, Wednesday, Thursday and Friday of this week, and a report of which will be found in our society proceedings for this week, proved to be the banner meeting of the organization.

The attendance amounting to over 2,600, was the largest ever recorded. It is the first time that the 2,000 mark has been passed. Many more New Yorkers than are usually seen were present and at the General Session it was announced by the President that all members of the New York State Society were formal guests of the Association and would have all the rights and privileges of the meeting. The various sections were very well attended and the interest aroused by the discussion of practical questions was very manifest.

One of the noteworthy features of this meeting was the enthusiastic subscription of some $6,000 to the Dr. Walter Reed memorial fund. After the announcement of the Rush monument committee that its labors were over, Dr. Wm. H. Welch stated in very forcible way the eminent suitability of having a proper memorial for the physician who succeeded in solving the problem of the eradication of yellow fever. After the preliminary announcements of subscriptions, among which the $500 from the California State Society and the $250 from Dr. Reed's brother officers were received with enthusiastic applause, the offering of subscriptions became contagious and over forty names were presented (see list in our account of the proceedings) with the promise of $100 and about one-half as many for $50. The work of the monument committee is to be vigorously pushed and the subject brought to the notice of Boards of Commerce and of Trade as well as large corporations, for Dr. Reed's work has definitely removed one of the great hindrances to commerce. It is thought that worthy commemoration of what he accomplished will thus be secured.

The scientific business of the meeting proved of much more than the usual interest, as was indicated by the attendance. At the medical section the discussion of typhoid fever on the first day showed that all are now agreed as to the necessity for the early diagnosis and surgical treatment of typhoid perforation. This diagnosis must not be made from the subsequent peritonitis but from the symptoms following immediately upon perforation. Dr. Osler considers that any sudden change in the condition of a typhoid patient must be made the subject of careful investigation.

Dr. Wilson, of Philadelphia, whose opinion as to the advisability of immediate operation for perforation in typhoid fever, announced nearly twenty years ago, is now a classic *locus* for comment, says that he hopes that the time will come when operations for the relief of severe and threateningly progressive hemorrhage in typhoid fever will be as common as are now the operations for intestinal perforation. It seemed a far away ideal, twenty years ago, that typhoid fever patients should, within two to three hours after perforation, be in the surgeon's hands, but the happy consummation has come with most gratifying results. Not to progress is to recede, and undoubtedly the next step will be the tying of bleeding arteries.

In the surgical section, while the surgery of the lower part of the abdomen with the inevitable appendicitis still continues to occupy a prominent place, there is a distinct trend toward a greater interest in the upper abdominal segments. Discussions were mainly occupied with various forms of enterostosis and with the surgery of stomach, biliary and pancreatic affections. In the

midst of these there came the consideration of one of the conditions—rupture of enlarged mesenteric glands—which simulate perforation of the intestines in typhoid fever. This is undoubtedly the condition the spontaneous cure of which has given rise to the impression that typhoid perforation is not necessarily fatal, even when no fecal fistula follows. Dr. J. C. Wilson described some cases of simulating perforation in typhoid which are related to these.

The new organization of the American Medical Association is now working smoothly and it is evident that close union of the various component bodies on a thoroughly representative basis is possible without undue expenditure of time in administrative effort and with the proper exclusion of clique politics. It seems that an era of splendid accomplishment for the profession is about to commence and that professional organization may be looked to with confidence for the prevention of many ills and the advancement of all legitimate interests.

THE TUBERCULOSIS CONGRESS.

An enthusiastic audience of nearly 500 physicians, representing the entire United States, greeted Dr. William Osler as he opened the "National Association for the Study and Prevention of Tuberculosis" last Monday night at Atlantic City.

Those who have this movement near at heart, and the entire medical profession comes within this category, should feel encouraged by the assurance that they are finally to have a Congress representative of the entire profession; that is, capable of doing work that is greatly needed.

At this meeting the work of organization was practically completed and a Board of Directors of thirty members appointed, committees formed and working plans projected.

As outlined in the Constitution and By-laws, the objects of this Association shall be: (*a*) the study of tuberculosis in all its forms and relations; (*b*) the dissemination of knowledge concerning the causes, treatment, and prevention of tuberculosis; (*c*) the encouragement of the prevention and scientific treatment of tuberculosis.

In another place we give a list of the officers and committees of the new body, and predict for this movement a success far beyond the anticipations of those who spoke last Monday night, at this memorable occasion, not the least among whom was Dr. E. L. Trudeau, the captain and veteran fighter of the "white plague."

ISOLATION OF TYPHOID GERMS.

For years past it has been the favorite object of bacteriologists to provide an easy method for the identification of the typhoid bacillus in the stools, or other products of the body, and likewise in water. With these attempts are associated the records of many more or less successful maneuvers, such as those of Elsner, Piorkowski, and others, which have successively been tried, and abandoned, because lacking the prime element of practicability. Even the latest suggestion—the lactose-crystal-violet-litmus mixture of Drigalski and Conradi—has failed to meet with the favor due to a really good and feasible method.

Nothing daunted, however, the German bacteriologists have kept faithfully at the irksome research, and have actually, it would seem, brought the solution of the problem within the reach of the profession—as a body of practical physicians, interested not in methods for themselves, but for their clinical bearing and results.

The new light has come out of the idea of Prof. Rubner, of Berlin, to investigate the action of the various alkaloids on the growth of typhoid and of coli. This resulted in Roth's discovery (*Hyg. Rundschau,* May 15, 1903) that caffeine exercises a markedly deleterious action on the coli group of bacilli, whereas it does not interfere with the development of the typhoid group, including the so-called paratyphoid organisms. The discovery, which in itself is not practically applicable, marked the point of departure of a further series of investigations, both by Roth, and Ficker and Hoffmann, looking to its clinical adaptation. The results of their investigations, which are embodied in the third number of the *Archiv für Hygiene* for the current year, must be characterized as extremely encouraging, and a very notable advance on all previous attainments.

As a matter of fact, they have asserted that it is possible with the methods thus elaborated by them to detect typhoid bacilli when these are present in the ratio of 1 to 53,000 of other forms. The essence of the method the details of which must be sought elsewhere, consists in the preliminary multiplication of the typhoid germs by cultivation for thirteen hours in a bouillon medium containing a fixed percentage of caffeine and of crystal violet. From the growth thus obtained in a medium especially favorable to the typhoid germ, cultures are made according to the method of Drigalski-Conradi, which allows of

their easy identification. Stools or water may be treated in this manner, and may be said, for practical purposes, to be typhoid-free, if they fail to react.

It is hardly necessary to dwell on the great importance of this advance in technic. It may be objected that the method is cumbrous and entails a delay of a day or more. These objections are valid, and certainly militate against the serviceability of the method as compared with that of the agglutination test, or of blood cultures as diagnostic criteria. On the other hand, it is undoubtedly true that the method is superior to the Widal, inasmuch as it gives positive results much earlier in the disease. Finally, the conditions which obtain in private practice are certainly far more favorable to bacteriological examination of the feces than of the blood—a fact which lends the new method an advantage which is none the less real for being purely accidental.

ECHOES AND NEWS.

NEW YORK.

Addition to the University and Bellevue Medical College.—In view of the large classes at the University and Bellevue Hospital Medical College, and the prospect for a very large entering class in the fall, the Council of New York University, at a meeting last Tuesday, determined to purchase land adjoining the new college building, on First Avenue, between Twenty-fifth and Twenty-sixth streets, and to proceed at once with the erection of a six-story fireproof building for the clinics and laboratories of the Medical College. The building will harmonize in general style with the building erected for the Medical College, on the corner of Twenty-sixth Street and First Avenue, in 1898, and will be of light brick with trimmings of Indiana limestone, a large part of the front being merely a framework of iron and glass in order to give the greatest possible amount of light for laboratory work. On the rear the building will adjoin the Carnegie Laboratory, which belongs to the University, and is used also for laboratory work. The first floor of the building will be given up to the free dispensary of the college, which is at present treating more cases daily than any other dispensary in the city, with one exception, the total number during the past year reaching 150,000 cases.

Transferred to the Police Department.—Dr. E. T. Higgins, who for three years has been a coroner's physician, was transferred to-day by the Municipal Civil Service Commission to the Police Department. Dr. Higgins is a graduate of the Bellevue Medical College. He has served as surgeon and physician at Bellevue, Harlem, and City Hospitals.

Changes in University and Bellevue Medical Colleges.—A plan presented by the medical faculty for an elective fifth year course for medical students, was approved at the meeting of the Council of the New York University. The following appointments were made: Phœbus A. Levene, M.D., Herter lecturer on pathological chemistry for session 1904-05; Stanley D. Curran, M.D., instructor in physical diagnosis; James H. Potter, M.D., instructor in physical diagnosis; W. Reid Blair, M.D., assistant in pathological histology; C. J. Anthony, M.D., assistant in physical diagnosis. Promotions in the corps of instructors were approved as follows: George B. Wallace, M.D., lecturer on pharmacology, to be assistant professor of pharmacology; Hermann A. Haubold, M.D., lecturer on clinical surgery, to be professor of surgery; Henry W. Wandless, M.D., to be chief of Clinic, Department of Ophthalmology; Robert J. Wilson, M.D., instructor in bacteriology, to be lecturer on bacteriology; William M. Ford, M.D., assistant to chair of surgery, to be instructor in surgery; Julius A. Becker, M.D., assistant demonstrator of anatomy, to be demonstrator of anatomy; Edward S. McSweeny, assistant demonstrator of anatomy, to be demonstrator of anatomy.

PHILADELPHIA.

Wills Hospital Clinics.—The Surgical Staff of Wills Hospital, Race Street, between Eighteenth and Nineteenth streets, Philadelphia, invites the delegates and members of the American Medical Association to attend a series of special clinics to be held at the hospital on Monday and Tuesday afternoons at two o'clock, June 13 and 14, immediately following the meeting of the Association in Atlantic City, N. J. On Monday afternoon, June 13, through the courtesy of the Board of City Trusts of Philadelphia, the privileges of the hospital have been granted to Prof. A. Maitland Ramsay, M.D., of Glasgow, Scotland, the official guest of the American Medical Association, who, under the guidance of Dr. Charles A. Oliver, will demonstrate and operate upon interesting cases occurring in the clinics of Drs. W. W. McClure, Oliver, Samuel D. Risley, S. Lewis Ziegler, and McCluney Radcliffe. In the evening, at 8.15 o'clock, a meeting of the Wills Hospital Ophthalmic Society will be held at the hospital, to which all ophthalmologists are invited. The subject for discussion will be "Enucleation and its Substitutes." Dr. George C. Harlan will preside. After the meeting an informal reception to Dr. Ramsay by the attending surgeons to the hospital will be held at the hospital. On Tuesday, June 14, Prof. Ramsay, under the guidance of Dr. Frank Fisher, will demonstrate and operate upon the interesting cases occurring in the clinics of Drs. Fisher, Conrad Berens, P. N. K. Schwenk, William Zentmayer, and William C. Posey. After the clinics, the assistant surgeons to the hospital will entertain Prof. Ramsay by a visit to Willow Grove Park for supper, music, and electric fountain display, returning to the city by eleven o'clock. Trolley cars for the park will leave the hospital door at five o'clock. All visiting ophthalmologists are more than welcome to join in the party.

Red Bank Sanitarium.—The twenty-eighth annual season of this outing place for poor children was opened Saturday, June 4. Addresses were made by a number of the officers of the association, and 2,000 children were entertained at the grove.

Dr. Hutchinson on Hospital Staff.—Dr. James P. Hutchinson has been elected a member of the surgical staff of the Pennsylvania Hospital to fill the vacancy made by the death of Dr. W. Barton Hopkins. Dr. Hutchinson, whose father was a well-known member of the hospital staff, had for some time been connected with the dispensary of the hospital.

American Climatological Association.—The following were elected officers of this society at the last annual meeting, held in Philadelphia, June 2 to 4, 1904: President, Dr. W. F. R. Phillips, Weather Bureau, Washington, D. C.; First Vice-President, Dr. S. G.

Bonney, Denver, Col.; Second Vice-President, Dr. S. D. Risley, Philadelphia, Pa.; Secretary and Treasurer, Dr. Guy Hinsdale, Hot Springs, Va.; Member of the Council, Dr. J. C. Wilson, Philadelphia; Member of the Executive Committee of the Congress of American Physicians and Surgeons, Dr. F. I. Knight, Boston, Mass.; Dr. R. G. Curtin, Philadelphia, alternate.

Finsen Laboratory to be Erected.—The University Hospital is to have a Finsen light apparatus in working order by the end of the year. An appropriation of $25,000 by the State will permit of the installation of the plant which will be placed in an additional story to the Agnew pavilion of the hospital.

CHICAGO.

Hydrophobia.—Director J. F. Biehn, of the City Municipal Laboratory, recently sent out a warning of danger of a hydrophobia epidemic. Muzzling all dogs that appear in public is the remedy advocated by him. The Chief of Police has issued orders for the muzzling of dogs. Dr. Biehn has just completed analyses of the bodies of three dogs, and has found that all had hydrophobia.

Causes of Mortality in War.—In a recent editorial in the Chicago *Tribune*, the causes of mortality in war were discussed, and among other things the editorial states that, of all wounds treated by medical officers of the union armies in the Civil War about four-tenths of 1 per cent., or 922 out of 240,712, were saber or bayonet wounds. In the Crimean war the English and French had 2½ per cent. of such wounds; in the Schleswig-Holstein war about 3 per cent., while in the Franco-Prussian war the records show that the Germans received less than one-third of 1 per cent. A striking commentary this upon the advance of modern military science, showing that with the general adoption of long range firearms the saber and bayonet are rapidly falling into disuse, and the time is coming, if it has not already arrived, when those old and honored weapons will become obsolete. But it is not the bullet or the artillery fire which strikes down the largest numbers of men. It is disease. In the Civil War one man out of every 6.7 was wounded in action; one of every 38 died of his wounds; one of every 42.7 was killed in action. Of the total mortality among colored soldiers 90 per cent. was from disease. Of the total mortality among the white volunteers, 70 per cent. was owing to disease; among the white regulars, 60 per cent.

Catholic Charities.—According to the will of the late Thomas Brennan, member of the Board of Education, he bequeathed $1,000 each to St. Joseph's Hospital, St. Elizabeth's Hospital, Mercy Hospital and Alexian Brothers' Hospital.

Prosecution of Hanish.—The State Board of Health has prosecuted Ottoman Hanish, charged with violating the medical practice act, by the use of "torture needles and lotus oil injections." A warrant has also been secured by the State Board of Health for the arrest of "Dr." August van Bysterveldt, who is charged with practising medicine without a license.

Smallpox.—The Department of Health directs attention to the fact that of the 80 cases discovered in Chicago since the first of the year, the most searching examination has failed to find a single one who had been properly or recently vaccinated.

Joint Meeting of the International Association of Railway Surgeons and the American Academy of Railway Surgeons.—A joint meeting of these two societies was held in Chicago, June 1, 2 and 3. The convention met in the Assembly Hall of Northwestern University. During the first day the sessions were presided over by Dr. James H. Ford, of Indianapolis, President of the International Association of Railway Surgeons, and the sessions of the second and third days by Dr. S. C. Plummer, President of the American Academy of Railway Surgeons. An Address of Welcome was delivered by Dr. Wm. A. Evans, of Chicago, which was responded to by Dr. George Ross, of Richmond, Va.

President Ford discussed the use and abuse of the railway surgeon in his Presidential Address; and President Plummer selected as the subject of his Address, "Following and Assisting Nature." Eighteen interesting papers were contributed by as many members and received appropriate discussions.

The following resoluton was introduced:

Resolved, That at the close of the present session, the International Association of Railway Surgeons dissolve its present organization for the purpose of organizing the American Association of Railway Surgeons, provided that a union be made with the American Academy of Railway Surgeons at the meeting set for that purpose.

Resolved, Further, That the Executive Board of this Association be authorized to join with the Executive Board of the American Academy of Railway Surgeons and organize the American Association of Railway Surgeons.

The resolutions were unanimously adopted.

The two Associations having dissolved, to become amalgamated into one Association, known as the American Academy of Railway Surgeons, the first order was the nomination of a temporary Chairman. On motion of Dr. Hollowbush, of Rock Island, Ill., Dr. D. S. Fairchild was elected temporary chairman. Dr. Louis J. Mitchell was elected Temporary Secretary.

Dr. A. I. Bouffleur, of Chicago, presented the report of a joint committee on Constitution and By-Laws, for governing the new organization, and on motion this report was accepted and adopted as read.

The following are the officers of the new organization, the American Academy of Railway Surgeons: President, Dr. John E. Owens, Chicago; Vice-Presidents, Dr. R. W. Corwin, Pueblo, Col.; Dr. G. D. Ladd, Milwaukee, Wis., and Dr. H. C. Fairbrother, East St. Louis, Ill.; Treasurer, Dr. T. B. Lacey, of Council Bluffs, Iowa; Secretary, Dr. H. B. Jennings, of Council Bluffs, Iowa; Editor, Dr. Louis J. Mitchell, Chicago; Executive Board: Dr. D. S. Fairchild, Des Moines, Iowa, and Dr. A. I. Bouffleur, Chicago, three-year term; Dr. S. C. Plummer, Chicago, and Dr. A. L. Wright, of Carroll, Iowa, two-year term; and Dr. W. S. Hoy, Wellston, Ohio, and Dr. J. R. Hollowbush, Rock Island, Ill., one-year term.

There was considerable discussion relative to the time for holding the next annual meeting, but this matter was left entirely to the Executive Board. It would seem from the suggestions made by different members that the meeting will be held next year, some time in the fall.

GENERAL.

List of Directors of Tuberculosis Association.—*Massachusetts*—E. O. Otis and V. Y. Bowditch. *Connecticut*—J. P. C. Foster. *New York*—S. A. Knopf, H. M. Biggs, E. L. Trudeau, and E. T. Devine. *Pennsylvania*—L. F. Flick, M. P. Ravenel, J. M. Anders, and J. S. Pearson. *New Jersey*—R. Hoffman. *Maryland*—W. H. Welch, William Osler, E. Jacobs, and J. S. Fulton. *District of Columbia*—G. M. Sternberg. *North Carolina*

—C. L. Minor. *Colorado*—F. E. Solly. *Illinois*—E. Klebs and R. H. Babcock. *Minnesota*—H. M. Bracken. *Missouri*—Wm. Porter. *Indiana*—J. N. Hurty. *Michigan*—V. C. Vaughan. *Ohio*—C. O. Probst. *California*—N. Bridge. *Texas*—M. M. Smith. *Marine Hospital*—General Walter Wyman. *Army*—Surgeon Bushnell, Fort Bayard. Others may be appointed by the present Board to make representation more complete.

Officers of National Tuberculosis Association.—President, Dr. E. L. Trudeau; Vice Presidents, Drs. William Osler, Hermann M. Biggs; Executive Committee, Drs. J. N. Hurty, E. O. Otis, E. Klebs, M. P. Ravenel, and Mr. E. T. Devine. Dr. Osler was made chairman of a committee of five to represent this Association at the Paris International Convention.

Constitution and By-laws of the National Association on Tuberculosis.—The Committee, appointed in Philadelphia on March 28, for the purpose of organizing a new Society for the Study of Tuberculosis, met at the house of Dr. Hermann M. Biggs in New York on April 22, and proposed the following Constitution and By-Laws to be submitted to those interested especially in the subject at a meeting in Atlantic City on June 6, 1904:

CONSTITUTION. *Article I.—Name.*—The name of this Society shall be The National Association for the Study and Prevention of Tuberculosis.

Article II.—Objects.—The objects of the Association shall be: (*a*) the study of tuberculosis in all its forms and relations; (*b*) the dissemination of knowledge concerning the causes, treatment, and prevention of tuberculosis; (*c*) the encouragement of the prevention and scientific treatment of tuberculosis.

Article III.—Meetings.—The meetings shall be held at such times and in such places as may be directed under the By-Laws.

Article IV.—Incorporators.[1]—The names and residences of the Incorporators are:

BY-LAWS. *Article I.—Membership.*—This Association shall consist of three classes of members: (*a*) Members; (*b*) Life Members; (*c*) Honorary Members. (*a*) Members: those persons who have participated in the organization of the Association at the meeting in Philadelphia on March 28, 1904, and such persons as shall from time to time be elected by the Board of Directors. The dues of members shall be $5 a year; (*b*) Life Members: Members may become life members upon the payment of $200; (*c*) Honorary Members: Persons distinguished for original researches relating to tuberculosis, or eminent as sanitarians, or as philanthropists who have given material aid in the Study and Prevention of Tuberculosis may be elected Honorary Members.

Article II.—Election of Board of Directors.—The Association shall at its first meeting elect a Board of twenty-five Directors, divided into five groups of five each, to serve one, two, three, four and five years, the duration of office to be determined by lot; thereafter, retiring Directors who have served a full term of five years shall not be eligible for re-election the year of retirement, provided, however, that this restriction shall not apply to the secretary or treasurer. At succeeding annual meetings five Directors shall be elected for terms of five years, or in case of vacancies in any of the groups for the unexpired terms.

Article III.—Election of Officers.—The Board of Directors shall annually elect from its own number a President, two Vice Presidents, a Secretary and a Treasurer, who shall be the officers of the Association as well as of the Board.

[1] It was voted, if feasible, that the Association be incorporated by an Act of Congress, and Dr. Sternberg and Dr. E. Jacobs were named a Committee to consider the best manner of carrying out this motion.

Article IV.—Committees.—Section 1. The Board of Directors shall appoint an Executive Committee of seven directors, of which the president and secretary shall be members ex-officio, to which shall be entrusted all the executive work of the Association. *Sec.* 2. The Board of Directors is empowered to appoint representatives on the International Committee on Tuberculosis; it shall also from time to time appoint such committees as may be necessary for scientific and educational work, and for the holding of meetings and congresses. *Sec.* 3. The Board of Directors shall make its own rules; the government of the Association, the planning of work, the arrangement for meetings and congresses, and all other matters appertaining to legislation and direction shall be in its hands; committees shall have the power to execute only what is directed by the Board.

Article V.—Quorum.—Seven Directors shall constitute a quorum of the Board of Directors.

Article VI.—Meetings.—There shall be at least one stated annual meeting of the Association at a time and place to be fixed by the Board of Directors. Other meetings of the Association may be called by the Board at such times as it shall deem proper. The Executive Committee shall hold stated and other meetings as may be directed by the rules of the Board of Directors.

Article VII.—Moneys.—The moneys received from membership dues and from all other sources shall be used for defraying the expenses of the Association, and for furthering its objects under the direction of the Board of Directors.

Article VIII.—Amendment of By-Laws.—The By-laws may be amended by the Board of Directors; for amendment a two-thirds vote of the entire Board shall be necessary. No amendment shall be adopted within thirty days of its proposal or without at least twenty days' notice of the meeting at which it is to be voted upon, which notice shall set forth the amendment in full.

American Dermatological Association.—At the twenty-eighth annual meeting of the American Dermatological Association, which was held at the International Hotel, Niagara Falls, on June 2 and 3, 1904, the following officers were elected for the ensuing year: President, Dr. William T. Corlett, of Cleveland, Ohio; Vice-President, Dr. Frank H. Montgomery, of Chicago; Secretary and Treasurer, Dr. Charles J. White, of Boston; Member of Council, Dr. John A. Fordyce, of New York. It was decided to hold the next meeting of the Association in New York City, on December 28, 29 and 30, 1905.

Patent Medicines and Postal Department.—Postmaster-General Payne recently made public the attitude assumed by his Department toward patent medicine advertisements in the mails. A large number of complaints having been received by the First Assistant Postmaster-General protesting vigorously against the United States mails being used for the purpose of circulating newspapers and other literature containing advertisements of alleged cures for loss of manhood, vitality, etc., the Acting Postmaster-General transmitted a number of these advertisements to the Assistant Attorney-General for the Post Office Department, with the request for an opinion as to whether or not their transmittal through the mails constituted a violation of law. Mr. Robb, the then Assistant Attorney-General for the Post Office Department, rendered an opinion holding such advertisements a violation of what is known as the "obscene law." The only intention which has ever been entertained by the administrative officers is to suppress the advertisements which the law officer of the Department has held to be obscene. Of course, the Post Office Department has never had any intention of starting a crusade upon patent medicines or of establishing a censorship upon advertisements printed in newspapers. There has been no change in the policy

or practice of the Department. The facts simply are that certain abuses having been called to its attention it has acted thereon as required by law. In the regular course of business in the office of the Assistant Attorney-General a number of cases were presented in which the so-called cures for lost manhood and lost vitality were complained of as being worthless, as well as the literature of the company selling the article being obscene. Analysis of these so-called remedies developed the fact that in most instances the ingredients were simply starch and sugar. In a number of instances the pills and drugs contained ingredients injurious to the system and forbidden by law to be sold. It having thus appeared that these companies were defrauding the public by means of false and fraudulent representations made through the mails, the issuance of fraud orders was recommended to the Postmaster-General and accordingly issued by him. No action has been contemplated by the Department save in those cases of obscenity and fraud.

Anti-mosquito War.—About fifty men are at work ditching the Hackensack meadows under the direction of the Board of Health, which has begun a war on mosquitoes.

OBITUARY.

Dr. Matthew Leepere died on June, of dropsy at the home of George Eastment in Glen Cove, Long Island. He returned recently from the Philippine Islands. He was born in Arkansas in 1854. At the age of eighteen he became Indian interpreter for the United States Government and three years later was made a commissioned officer of the Fourth United States Cavalry. For ten years he saw active service in the West and on several occasions received honorable mention for bravery in battles with the Indians. At the expiration of the ten years he retired from the army and took up the study of medicine. He subsequently received diplomas from three medical colleges. He made a specialty of throat and ear diseases. He went to Chicago in 1882 and remained there until the Spanish War broke out, when he enlisted as a volunteer surgeon. He remained in the army until the close of the war in the Philippines. For the last year and a half he had been president of the Board of Health of the island of Mindoro. He was enthusiastic over the Philippines, and believed there were great possibilities for the islands. He was taken sick on Jan. 1, and as his condition did not improve he decided to return home.

Dr. George Washington Brooks died in this city June 3, at the age of eighty-seven years. He retired from active practice eight years ago and spent his time since then in country resorts and partly in sanitariums, as he suffered four strokes of apoplexy, the last of which proved fatal. Born in Portland, Me., Dr. Brooks came of a distinguished family. His brothers, James and Erastus, were the editors of the old *New York Express*. Mrs. Brooks, who was Miss Jane Roberts, of Utica, and one son, Dr. George Frederick Brooks, survive him.

Dr. Anna E. Park, whose charitable work of twenty-seven years caused the poor of the west side to know her as "The Good Doctor," died of pneumonia on May 30, at her home, 367 West Twenty-third street, New York. Her illness was contracted five days previously, while she was attending a poor patient. The doctor was born in Connecticut seventy-two years ago and was graduated as an eclectic in Philadelphia in 1860. During the war she served as a Red Cross nurse, and was a member of the National and New York State Eclectic Societies.

Dr. Frederick C. Schaefer, professor of clinical surgery in the Chicago Post-Graduate Medical School, surgeon-in-chief of St. Hedwig's Hospital, and gynecologist to St. Elizabeth's Hospital, died suddenly June 3, at his home in Chicago, from acute gastritis. He was born in Galena, Ill., in 1849, and came to Chicago in the early seventies. He received his professional training in the Chicago Medical College. After being graduated, he became professor of anatomy. When the institution was merged with Northwestern University, Dr. Schaefer continued as a member of the Faculty. At the time of his death he was also consulting surgeon to the Mary Thompson Hospital for Women and Children. He was a frequent contributor to medical journals. He was also a member of the American Medical Association, of the State and local medical societies. He leaves a wife, one son, and three daughters.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, held at Atlantic City, N. J., June 7 to 10, 1904.

General Session, June 7, 1904.

At the first General Session the annual meeting of the American Medical Association was formally opened by prayer by the Rt. Rev. John Scarborough, Bishop of Trenton, of the Protestant Episcopal Church. After addresses of welcome to the Association by State officials of New Jersey and of the Mayor of Atlantic City, and the response by the First Vice President of the Association, Dr. G. C. Savage, of Nashville, Tenn., the committee of arrangements announced the very full program of social events which had been prepared.

The important business of this first General Session was the introduction of the subject of the Dr. Walter Reed Memorial and the beginning of the subscriptions to it with an enthusiasm that would seem to promise a speedy realization of the amount originally proposed for the memorial and with an inspiration that would seem to show the possibility of exceeding first intentions.

Worthiness of the Object.—Dr. William H. Welch, of Baltimore, said that no worthier object could possibly be proposed for the consideration of Amercian medical men. Dr. Walter Reed was entirely a product of American training methods in medicine. His success may be said to be due to the typical American spirit of enterprising invention put at the service of medicine. What he accomplished is one of the greatest advances in medicine. The only thing it can possibly be compared to is the conquest of smallpox by vaccination. For his discovery of the mosquito doctrine of the distribution of yellow fever will lead to the total eradication of that disease eventually, as it has already completed what looked like the hopeless task of ridding Cuba completely of the affection which was supposed to be indigenous in the very soil, for it had been known to exist continuously for over a century.

National and Popular not Medical.—Dr. Welch said that the memorial to Dr. Reed should be worthy of this marvelous accomplishment. For this purpose it seems well to make appeal not only to the narrow circle of medical interests but to the business interests generally throughout the country. Boards of Trade and Commerce should be brought to see how much was accomplished by one man and would then realize the eminent suitability of giving him a proper memorial. To say nothing of the number of lives that have already been saved and will be in the future and the immense amount of human suffering spared, there is the further consideration, so unworthy to be placed beside the humanitarian motives, yet not without its weight, that economic advantages of great moment will flow from

it. It has been calculated that the last serious epidemic of yellow fever—that of 1878—cost this country several hundred millions of dollars. Now we know that through Dr. Reed's work this useless expense will never be called for again.

Honor to Medical Men.—Dr. Theodore Diller, of Pittsburg, Pa., said that all classes of public benefactors seem to receive recognition before the great medical discoverers. The commanders and other heroes of our wars, the Judges and literary men, all receive their memorials at the hands of the public, but the doctor, as is so often the case in private life, is forgotten. In England, however, Jenner, the discoverer of vaccination, has been worthily honored by English professional brethren; it seems but right that for as worthy an object American physicians should be ready to unite. It has taken long to raise the monument to Rush, but at last it is accomplished. May the greater union among the medical profession in this country now be typified by the better success of the monument movement for Dr. Reed.

Enthusiastic Subscriptions.—Dr. W. W. Keen, of Philadelphia, then announced that the committee was ready to receive subscriptions and gave the names of a number of ex-Presidents of the American Medical Association who had expressed their willingness to contribute $100 each to the fund. After this list other names were announced and from all over the large hall subscriptions poured in. Nearly $7,000 was subscribed within a quarter of an hour. The California State Medical Society subscribed $500. The officers of the United States Marine Hospital Service, on duty in Washington, many of whom had been personally acquainted with Dr. Reed, and some intimately associated with him in his work on yellow fever, subscribed $250. Subscriptions of $100 each were received from the following: Dr. C. A. L. Reed, of Cincinnati, John A. Wyeth, of New York, Dr. W. W. Keen, of Philadelphia, Pa., H. O. Marcy, of Boston, Mass., Surgeon-General Sternberg, Surgeon-General Wyman, of Marine Hospital Service, Dr. Jos. D. Bryant, of New York, Dr. E. G. Janeway, of New York, Dr. Frederick C. Shattuck, of Boston, Dr. Arthur T. Cabot, of Boston, Dr. Joseph Matthews, of Louisville, Dr. H. C. McCormack, of Kentucky, Dr. Wm. H. Welch, of Baltimore, Dr. A. A. Smith, of New York, Dr. William Osler, Baltimore, Dr. A. H. Smith, of New York, Dr. Victor C. Vaughan, of Ann Arbor, Mich., Dr. H. A. Kelly, of Baltimore, Dr. Jno. H. Musser, of Philadelphia, Dr. S. Weir Mitchell, of Philadelphia, Dr. Wm. J. Mayo, of Rochester, Minn., Dr. Francis Kinnicutt, of New York, Dr. J. B. Murphy, of Chicago, Dr. H. O. Walker, of Detroit, Dr. Palmer Dudley, of New York, Dr. J. C. Wilson, of Philadelphia, Dr. Floyd McRae, of Atlanta, Ga., Dr. Chas. G. Stockton, of Buffalo, N. Y., Dr. Abraham Jacobi, of New York, Dr. Robert F. Weir, of New York, Dr. George Ben Johnson, of Richmond, Va., Dr. Jos. Peterkin, of Seattle, Wash., Dr. DeLancey Rochester, of Buffalo, N. Y., Dr. Barlow, of Los Angeles, Cal., Dr. Alvin Hubbell, of Buffalo, N. Y., Dr. Mackenzie, of Portland, Ore., Dr. A. MacLaren, of St. Paul, Dr. W. S. Halsted, of Baltimore, Dr. Kober, of Washington, D. C., Dr. C. J. McClintock, of Detroit, Mich., Dr. Rosa Wiss, of Meridian, Miss. After these a number of subscriptions of $50 were received. The committee expressed its intention of giving those interested in commerce with tropical ports an opportunity to subscribe, since none benefited more than they by Dr. Reed's discovery.

The session closed with the introduction of the new president, Dr. John M. Musser, by Dr. Billings, and the delivery of the President's Address which will be found on page 1105 of this week's issue of the MEDICAL NEWS.

SECTION ON MEDICINE.

FIRST DAY—JUNE 7TH.

The Adaptation of Pure Science to Medicine.—The scientific business of the Section on Medicine was opened by the address of the Chairman of the Section, Dr. Alexander Lambert, of New York, with the above subject. He reviewed some of the details of recent progress in medicine. Tetanus, for instance, has been demonstrated to spread along the nerves and so there has come the idea that instead of being injected directly into the circulation where it is so much diluted the antitoxin might be expected to do its work of neutralization more effectively if placed in a position to follow the same paths. Dr. Lambert has seen two patients with tetanus treated by the direct injection of the antitoxin into the nerve bundles with successful results. As in both cases the severity of the initial symptoms seemed to make the prognosis very unfavorable, if not absolutely fatal, the new method of treatment will deserve to be followed with attention, so as to determine its absolute value.

Preventive Inoculations.—This subject, though followed with such hopeful anticipations at the beginning, because of the analogy with vaccination, has proved very disappointing. There are, however, some results that are encouraging. Preventive inoculations for typhoid fever seem to have been followed by some good results. Statistics apparently establish that fifty per cent. of those who are exposed to typhoid fever after inoculation and who would have, according to the chances of the conditions, taken the disease prove able to resist it. On the other hand fifty per cent. of those who take the disease after inoculation have it in very mild or even abortive form, and the mortality is much lower among the inoculated than among the rest of the population.

The Widal Test.—The agglutination reaction has proved of great diagnostic value when positive, but when negative nothing can be argued from the fact. The agglutinative power bears no relation to the severity of the disease nor does it tell anything as to resistive powers or as to the prognosis of the case. In severe cases it may be less marked than in those of mild type, and it may even decrease with the severity of the symptoms. During convalescence it may be more marked than at the height of the disease. Unfortunately, in certain cases what one pathologist will declare to be a positive reaction, another may consider as of negative significance, and some have even taken to use the expression, doubtful reaction, which is to be deprecated. The laboratory is often unable to make the diagnosis and this fact should be frankly stated, as otherwise there may be an increase of the suspicion of the pathologist by the clinician which unfortunately exists and which sometimes leads to specimens being submitted without the data that can help the pathologist and to which he has every right.

Lumbar Puncture.—This diagnostic aid has proved especially serviceable in the recent epidemic of cerebrospinal meningitis for the differentiation of that disease from the other forms of meningitis and has besides proved of some value from the standpoint of treatment. This method of diagnosis is the only one that can show with certainty the presence of sporadic cases of the disease when no epidemic is in progress.

Chemistry of the Urine.—In this there remains most to do. The presence of albumin and casts is helpful only in a general way. No direct connection exists, as Dr. Cabot has shown, between the urinary findings under present methods and the post-mortem observations. The difference between acute and chronic conditions can in general be recognized but scarcely more

than this. On the other hand, nothing definite as to prognosis can thus be determined. Uremia may supervene quite unexpectedly, even where the patient has been carefully watched. The real causation of uremia is not yet understood. Anuria may exist for some days and cause the death of the patient from failure of the kidneys to remove excrementitious material, yet no uremic symptoms manifest themselves. The total solids in the urine seem, however, to be a better indication of the possibility of uremia than the albumin. In this matter much remains to be done, and much that has been apparently accomplished has had to be undone when brought to the test of actual practical experience. Eclampsia has usually been considered, until quite recently, to be a form of uremia incident to the pregnant state. Its occurrence, however, bears no relation to the presence of albumin and casts in the urine, for it has been known to develop when these were not noted and, on the other hand, some patients with considerable albumin and casts pass through pregnancy without a symptom of eclamptic character. Recent investigations seem to show that eclampsia is connected with a condition of the liver not unlike the pathological process which, in more advanced cases, is known as acute yellow atrophy of the liver. Some liver degeneration seems a not unusual accompaniment of pathological pregnancies and even such conditions as hyperemesis—the pernicious vomiting of pregnancy—may be connected with liver change of some kind. These are the problems now before the medical profession for solution.

Pernicious Anemia and the Stomach.—Dr. Charles G. Stockton, of Buffalo, presented an analysis of 24 cases of pernicious anemia. In the majority of the patients there were some digestive disturbances. At times not gastric alone but also intestinal. Some of the patients had anorexia as a prominent symptom but most of them had reasonably good appetite. Most of the cases of true pernicious anemia present the symptom achylia gastrica; that is, there is no formation of chyle in the stomach and no gastric digestion. There is no hydrochloric acid in these cases and, in the range of Dr. Stockton's experience, once HCl has disappeared it does not make its appearance again. The appetite and general condition may improve in correspondence with an improvement of the blood condition but gastric digestion remains as before.

Achylia Gastrica.—In his studies of achylia gastrica, Dr. Stockton has not found that this is by any means necessarily connected with pernicious anemia. He has seen cases of it which have existed for many years without any tendency to the production of anemia of the pernicious variety, though when the symptom-complex is associated with dairrhea, then there is secondary anemia. When achylia gastrica exists alone, the motor sufficiency of the stomach is intact; and so long as the viscus is able to pass on the food which it contains, no difficulty is experienced. At times there seems to be even an increase of stomach motility. In pernicious anemia an increase of the stomach motility is sometimes noted, but, later, this is apt to become weaker, apparently as the result of the changes in the blood, not supplying sufficient nutrition to the stomach wall.

Cardiac Symptoms.—The most interesting feature of pernicious anemia is the slight amount of cardiac disease which exists in connection with the severest pathological conditions of the blood. Even hard workers do not complain much of their hearts and do not suffer discomfort in their hearts, or, except for a certain amount of dilatation, are there any physical signs. Hemic murmurs exist very often, but they are not as common as in chlorosis. They are to be found over the large vessels and in the systolic sound of the heart. They change very much with the varying conditions of the patient's blood and may even disappear during intermissions of the disease. Since Dr. Billings called attention to the fact that spinal symptoms are common in connection with pernicious anemia Dr. Stockton has found in six out of nine cases studied for this detail that they were present. There is usually an absence of any history of severe illness in the patient's past. As a rule the first symptom that is complained of is dyspnea and this is one of the commonest symptoms of pernicious anemia. Many cases of the disease are missed. Patients come with the story that they are suffering from cancer of the stomach or liver trouble, or heart disease, or locomotor ataxia. Most of these diagnoses have been confirmed by physicians who seem not to have suspected the existence of pernicious anemia, though a single examination of the blood would have revealed the presence of the disease.

Duration of the Disease.—One of Dr. Stockton's patients died in five years after a definite diagnosis of pernicious anemia could be made. One of them, on the other hand, lived only six months, but then it is not easy to determine how long the condition may have existed and may have been latent. Some other statistics of the disease are interesting. In 22 patients there was a lemon-yellow color of the skin. In only two was the characteristic yellowness absent. In some of the cases the patients had the look of being jaundiced and the diagnosis of their condition would have been difficult only for the blood examination. Very few patients suffering from the disease have a coated tongue. In 19 out of the 24 patients, there was a denuded tongue, the outer cells having died for lack of nutrition.

Hydrochloric Acid a Luxury.—Dr. Richard Cabot, of Boston, in discussing Dr. Stockton's paper said that in a careful study of 151 cases of pernicious anemia he had found hydrochloric acid absent in about five sixths of the cases. Most of these patients, however, had perfectly good digestion, in fact it was surprising how many of them were able to stand even forced feeding and yet have no stomach discomfort. As a result of his studies, Dr. Cabot came to the conclusion that hydrochloric acid is a luxury in digestion, but by no means a necessity. So long as there is no motor insufficiency of the stomach, patients have no inconvenience from their achylia gastrica. Dr. Cabot also has noticed that hydrochloric acid is absent during periods of improvement in pernicious anemia. The most surprising thing, in his experience, however, is the slight cardiac symptoms, even in the advanced stages of the disease when the clinician cannot help but know that the heart muscle is in a state of severe fatty degeneration.

Gastric Atrophy and Pernicious Anemia.—Dr. Max Einhorn, of New York, said that pernicious anemia is not due to gastric adynemia. There is no direct connection traceable either of cause or effect between these two conditions. There seems no doubt, however, that atrophy of the stomach wall does occur as a consequence of the poor blood that comes to it. Achylia gastrica, however, may exist with an excellent general condition and without any severe changes in the blood. Cases of it have been followed now for many years without any serious consequences being noted in other systems of the body.

Dr. Allen Jones, of Buffalo, said that it is a clinical fact that pernicious anemia is not caused by achylia gastrica. He has in his laboratory work seen much more achylia gastrica without pernicious anemia than with it.

Gastric Atrophy and Pernicious Anemia.—Dr. William Osler, of Baltimore, said that it was surprising how good the condition of patients may be who are suffering from pernicious anemia. They bear forced feed-

ing very well without any stomach distress, and the fatal issue is often surely not connected with any stomach lesion. On the other hand, stomach symptoms are a frequent accompaniment of pernicious anemia. The first symptom of the disease is often noticed in the stomach. There cannot help but be an impression that this organ is of importance in the production of pernicious anemia under certain circumstances. When very severe atrophy of the stomach exists, such as was described by Osler and Henry some years ago, then this would seem to be a cause of the blood condition. In this case described, the mucous membrane of the stomach had become cuticular. It had entirely lost the character of a secretory membrane. Dr. Osler said that he would be interested to know if observers of pernicious anemia found any connection between the disease and the septic condition of the mouth which had been described by certain English observers and reported as a cause of the disease. Dr. Osler himself has seen this spring so many cases of pernicious anemia as almost to constitute an epidemic of the disease. In all cases in recent years he has looked for oral sepsis, but has not found it in any notable proportion of cases and considers that it has little to do with the etiology of this type of anemia.

Diagnosis.—Dr. Osler does not consider that it is creditable to the diagnostic skill of physicians in this country that so many cases of pernicious anemia should be missed by ordinary physicians, leaving the recognition of the disease for the consultant. Laboratories are at hand now in nearly every part of the country and blood examinations can readily be obtained. There are surely enough symptoms in pernicious anemia, apart from the blood, to make at least a suspicion of its existence occur to the practitioner's mind. Too many physicians, however, are satisfied with general ideas, and the consequence is that cases of pernicious anemia masquerade as all sorts of affections.

Hydrochloric Acid Supplied.—Dr. J. N. Hall, of Colorado, said that in certain cases of pernicious anemia, in which arsenic failed to do good, he had tried the use of rather plentiful amounts of hydrochloric acid. The rationale of the administration of this is to make up for the absence of hydrochloric acid which is so commonly noted. In at least one recent case, in which everything else had failed, the patient became practically cured and has remained in good condition since. In one case where Fowler's solution failed to be of any service, Dr. Hall found subcutaneous injections of cacodylate of soda of excellent effect. The patient was a physician. The improvement took place several years ago and he has remained well ever since. Dr. Hall considers that in cases where the pernicious anemia may be suspected of being a secondary anemia due to the presence of intestinal parasites, the absence of eosinophile cells makes it very clear that the affection is not due to a parasite.

Large Doses of Hydrochloric Acid.—Dr. George Dock, of Ann Arbor, Mich., said that hydrochloric acid, fresh air, abundant diet, just as if one were treating the patient for tuberculosis, constitute, in his mind, the most effective regimen for pernicious anemia. Of course it is doubtful whether this accomplishes anything more than arsenic does, or whether the patients are really improved, for there are cases in which without any special therapeutic effort, pernicious anemia seems to get much better. The disease is very uncertain in these intervals of improvement. Dr. Dock considers that when hydrochloric acid is used, it should be administered in large doses. Forty-five to 60 minims should be taken well diluted after meals. When the drug is well borne, the patients improve under it. When it is not well borne, it is ineffective. Dr. Dock considered that the gastric digestion and its chemical tests should be controlled by thorough examination of the stools. It is hard, however, to determine the relations between the feces and the ingesta, and this is a problem that remains to be worked out.

Gastric Atrophy and Pernicious Anemia.—Dr. Stockton, in closing the discussion, said that he feels his own conclusion with regard to the absence of connection between the gastric condition and pernicious anemia to be wrong if Dr. Osler insists on the etiological relationship. With Dr. Einhorn, however, Dr. Stockton prefers to consider the gastric condition an effect rather than a cause. He doubts about the success of any therapeutic effort for pernicious anemia and has seen about as many cases improve without arsenic as with it. The disease is entirely too uncertain in its course to be made a subject for any definite statistics as to therapeutic results.

Perforation in Typhoid Fever.—Dr. Morris Manges, of New York, reported 19 cases of perforation in typhoid fever out of the total of over 200 cases observed at Mt. Sinai Hospital during the last two years. Sixteen of these patients were operated upon and five of them recovered. Three of the patients were not operated upon for lack of consent to do the operation, and one of the three recovered. In all of the 16 operations the diagnosis was confirmed at the operation. There was no doubt at all of the perforation in the other three cases, in two of which it was observed at autopsy, and in the third demonstrated by a subsequent fistula. Dr. Manges considers that the present treatment of the subject of perforation in typhoid fever, in text-books is old fashioned and not likely to help the general practitioner to make the diagnosis early enough to enable the surgeon to save life. What needs to be diagnosed is the perforation itself and not the subsequent peritonitis, which is almost sure to be the forerunner of a fatal termination, if it has become generalized.

Symptoms of Perforation.—The most prominent symptom is pain which occurs in practically all cases unless the patient is in a comatose condition. Rigidity is the next most important symptom. In 16 of the patients there was an intermittent tendency to rigidity in two. Distention of the abdomen, often considered a common symptom, was found in a little more than half the patients, while eight of them presented even a retraction of the abdominal walls. The movable dulness, said to occur in the flanks in perforated patients, is not a valuable diagnostic aid and occurs too late to be of service for surgical intervention. It would be much more important for hospital physicians to occupy themselves with the size of the liver rather than to waste time in finding out whether the spleen is enlarged or not. The liver dulness should be determined in the axillary line, as there it is less likely to be encroached upon by the gaseous distention of the colon.

Critical Symptoms.—The pulse fell in none of the patients and rose in 12. In seven patients only was leucocytosis present and only in one patient were symptoms of collapse noted. Twice the patient began to sweat profusely immediately after the perforation. No disturbance of blood pressure was noticed in any of the cases, though during the past winter especially careful observations were made with regard to this point. It must not be forgotten that the onset of symptoms is by no means necessarily coincident with the perforation. As Dr. Shattuck, of Boston, has shown, there may be slight attacks of pain which pass off perhaps more or less and then are followed by definite symptoms after some hours.

Pain the Pathognomonic Symptom.—In 14 of the 19 patients studied, pain was noted. This was paroxysmal at times, but by no means in all. It was so severe that even patients in coma cried out at times, in others it

was quite mild. It is constant in some cases and in others it disappears after a time. If the patient is anxious about the outcome in a mild case, the symptom may be concealed. In one instance, at the Mt. Sinai Hospital, two patients side by side suffered from perforation. As soon as the first occurred, he was removed to the operating room and accordingly when pain came to the neighboring patient he refused to say anything about it. It is not easy to understand the significance of the pain. In some cases there is hemorrhage associated with it. In others this is not the case. There is danger in the use of opium lest it should mask the symptoms.

Spontaneous Cure.—The fact that one of the three patients who refused operation recovered, shows the possibility of spontaneous cure, which has, however, been pointed out by other observers before, and under the best possible conditions, however, only 5 per cent. of the patients recover spontaneously after perforation. Even these recover, however, with the unpleasant accompaniment of a fecal fistula. Thus it would seem an operation is not only justified, but eminently indicated. There need be no fear of the effect of the anesthetic. In Dr. Manges' cases, the anesthesia had proved a stimulant, and general anesthesia had been found much better in its effect upon the patient than local anesthesia with the shock and worry of it all. In concluding his paper, Dr. Manges said that Dr. Wilson, of Philadelphia, in 1886 and Dr. Mikulicz had pronounced very definitely in favor of operation for perforation. Now, after a score of years, their words are the best possible advice that can be given.

False Conservatism.—Dr. Osler said that he heard Dr. Wilson pronounce, nearly twenty years ago, in favor of operation for perforation in typhoid fever. He must have been older then than he is now, for at once a revulsive feeling of conservatism came over him. Fortunately, however, he was able to overcome it, and the result has been for the benefit of many patients. The only way to recognize perforation is to watch for the symptoms, and any possible change in them.

Dr. Osler said that any change in the condition of a typhoid patient must be reported at once. To leave such things until the daily rounds or at the mercy of any routine is almost sure to be fatal. Within ten minutes the patient should be under the physician's eye and the surgeon should be asked to cooperate if everything is not right. House surgeons should be ready to operate in such emergencies at night or where there is delay in reaching the attending surgeon. The last perforation at Johns Hopkins Hospital was in a stalwart German seen in the ordinary rounds at 11 A.M. At 12 M. there was a sudden attack of pain; by 3 P.M. he was operated on. This apparently had no effect on the regular course of his typhoid fever.

Operation for Hemorrhage.—Dr. J. C. Wilson, of Philadelphia, said that he hoped the time would come when operation would be done for threateningly fatal hemorrhage in typhoid just as it is now for perforation. Hemorrhage and perforation are not coincident in Dr. Wilson's experience, though it is not uncommon to have perforation follow severe hemorrhage. Pain as a sign of perforation is not absolutely to be depended on. Some cases of typhoid present severe pain sudden in onset, the effects of which pass off in a few hours without any sign of harmful result. The differentiation of these cases must give the medical man time to pause before determining upon surgical intervention without some other sign to confirm it.

Difficulty of Locating Bleeding Point.—Dr. Morris Manges, in closing the discussion, said that he hoped Dr. Wilson's recommendation as to hemorrhage would accomplish as much as had his announcement of the policy to be followed after perforation. He would have to show the profession how to locate the bleeding point, however, for, as it is now with all the freedom of examination furnished by the opportunities of the dissecting table, it is often difficult to find the source of the hemorrhage.

Uterine Hemorrhage in Typhoid.—Dr. William E. Darnell, of Atlantic City, reported a case in which the fatal issue in an anomalous illness, during the course of which there had been but moderate fever, was brought about by severe uterine hemorrhage. No source for this could be found in the genital tract. Examination of the colon, however, showed the typically enlarged and ulcerous Peyer's patches, characteristic of typhoid. The question was then raised whether this might not be the causative agent in the hemorrhage.

Increase of Pneumonia.—Dr. Edward F. Wells, of Chicago, showed from statistics the great increase of pneumonia during the past century. About eight per cent. of all the deaths are now due to this affection. Far from decreasing, with our knowledge of infectious disease, it has multiplied in spite of knowledge. During the last decade of the nineteenth century it was probably three times as frequent as during the earlier decades. This is due partly to the greater virulence of the pneumococcus, but partly also to the more frequent opportunities for infection presented by great city life. Closer contact causes its spread, for it is undoubtedly a contagious disease in the strictest sense of the term. As the result of passing through a number of susceptible people the pneumococcus gains in virulence and thus is able to overcome the more or less immunity to it presented by many individuals. Dr. Wells has succeeded in demonstrating the pneumococcus to be present in the throat and nasal secretions of over forty-five per cent. of normal, healthy individuals out of over 100 examined. The organism plainly is taken up from the air and lodges here. Under the effect of cold the mucous membrane becomes paretic and so is not able to throw off the microbe. When it finds its way into the pulmonary alveoli, conditions become favorable for its growth. In a certain number of cases the pneumococci find an entrance into the lungs through the circulation. Hence the necessity for caring for conditions of tonsillitis as well as all catarrhal conditions of the nose and throat, which favor the lodgment of the germs. Honeycombed tonsils seem to present an avenue of entrance often available for the repeated attacks of pneumonia seen in some persons. Such mechanical and pathological conditions are much more important factors in the etiological predisposition of the disease than perhaps even the susceptibility of which so much has been made. Besides the virulence of pneumonia, Dr. Wells is confident that there is a definite increase of mortality from the disease, according to the number of cases. This also is due to the greater virulence acquired by the pneumococcus.

Prophylaxis.—Dr. Wells considers that the only way to lessen the present mortality and prevent even further increase of the disease is to avoid as far as possible the distribution of the secretion of patients suffering from the disease. The sputum and nasal secretions and all articles that become soiled with them must be thoroughly disinfected. This includes especially the fingers and the bedding of patients and requires the thorough disinfection of rooms in which such patients have been. The most important individual measure of prophylaxis is undoubtedly the avoidance of respiratory disease, for this predisposes the pulmonary mucous membrane to allow the lodgment of the pneumococcus. Dr. Wells considers that the blood pressure is an important element in pneumonia as regards both prognosis and course of the case. At the beginning there is always

a period of lowered blood pressure. Later this is not so common. This lowered blood pressure seems to Dr. Wells to be probably due or at least to be one of the elements of the physiological process by which leucocytes escape from the blood-making areas. It is now generally conceded that leucocytosis in pneumonia makes a distinctly favorable prognosis. Accordingly it would seem that this should be encouraged. In Dr. Wells' hands, the most efficient agent for the encouragement of leucocytosis with lowered blood pressure has been veratrum viride. This should be used in sufficient quantities to lower the pulse rate. If at the beginning of the case there is high blood pressure, bloodletting is of very great service.

Venesection in Pneumonia.—Dr. Jenkins, of Iowa, said that undoubtedly something of the frequency of pneumonia in recent years is due to the epidemic of influenza which has made many individuals more susceptible to respiratory disease than before. The treatment of pneumonia on the expectant plan has certainly not been satisfactory. The average mortality is higher than before. It would seem then that bloodletting should be reverted to once more, and that where the fever constitutes an important complication, this should be reduced by means of cold water.

Symptoms Not to be Treated.—Dr. De Lancey Rochester, of Buffalo, N. Y., said that it is an unfortunate thing to suggest treatment for symptoms, since it is the individual and the special form of pneumonia with its complications that must be treated. Poisons are already in the system, and it is important not to add to these by giving remedies that are also poisonous. Early bleeding should be resorted to in sthenic cases. Venesection is also of importance later on in the disease if there should be dilatation of the heart from weakness. Dr. Rochester does not believe in the use of opium in pneumonia, since it locks up the secretion, thus adding to the toxemia which is always a source of danger, besides it masks the symptoms, preventing the physician from realizing the danger the patient is in. One important method of elimination of toxins is sweating. This should not be brought about by the introduction of diaphoretic drugs, which are usually of depressant not to say poisonous nature. Hot foot-baths, properly given, without any disturbance of the patient, that is, while lying in bed, and hot air-baths, will be found quite efficient for this purpose, and will often be of distinct service in toxemic cases. Late pulmonary edema in this disease seems to be due to failure of the right auricle, and the first sign of it should be an indication for venesection.

Series of Pneumonia Cases.—Dr. Joseph Sailer, of Philadelphia, reported a series of 60 cases of croupous pneumonia, studied with special reference to certain physicial signs and to the laboratory diagnosis with discussion of the value of leucocytosis and the quantity of estimation of the chlorides in the urine. Dr. Sailer noted particularly the frequency of pneumonia of the upper lobes in fatal cases. With regard to leucocytosis the conclusion reached was different to the general impression with regard to this phenomenon. Three of the patients that recovered had less than 10,000 leucocytes, ten had 10,000 to 20,000, five 20,000 to 30,000, five 30,000 to 40,000, and three over 40,000. On the other hand, four of the patients who died showed a leucocytosis of 20,000 to 30,000, one had over 30,000, and one of the thirty patients had nearly 50,000 leucocytes during the course of the disease. No definite conclusion then can be reached with regard to the significance of leucocytosis. Where leucocytosis is absent, fatalities ensue more frequently, but a high leucocyte count does not give a favorable prognosis. Any method of treatment, therefore, that would be founded on this phenomena would not likely be of great advantage.

Urinary Chlorides.—The chlorides in the urine are not of prognostic value. When in the early course of the case the chlorides are absent, patients usually die, but they may be present and yet fatalities ensue. The presence of chlorides in pneumonia is very different from that of typhoid. They are always reduced in pneumonia while usually not disturbed at all in typhoid. This point can be used as a diagnostic factor in obscure cases of pneumonia. In this way a central pneumonia which gave no physical signs at any time, was recognized, and the diagnosis confirmed at autopsy. Icterus was noted three times in 60 cases, but seems to have no special connection with the pneumonia itself. Cyanosis was noted in severe form twice and was relieved once by venesection. Skoda's indeterminate breathing was noted in certain cases. It seems of diagnostic value.

Antipneumococcus Serum.—In ten cases antipneumococcus serum is employed and the results obtained are distinctly favorable. Four of the patients which recovered were so unfavorable in their prognosis that their recovery seemed marvelous. Three deaths took place. These were, however, in patients who would surely not have survived any form of treatment. One of them recovered from the pneumonia, but died shortly after from rapid tuberculosis. The results can be said to be fairly satisfactory, but further observations must be made to test the value of the serum.

Pulmonary Edema.—Dr. Babcock, of Chicago, said that the development of pulmonary edema in pneumonia patients after the crisis has passed, points to the failure of the right heart. Bacelli's suggestion, however, that the pneumococci may find lodgment in the walls of the alveoli must not be forgotten, for this seems to be the cause of the edematous condition. The blood pressure in pneumonia is low from the beginning, and this would seem to contraindicate the use of veratrum viride. The theory that lowered blood pressure helps leucocytosis is after all as yet unsubstantiated, and, besides, the value of leucocytosis itself as a feature of pneumonia is not determined. Stimulation seems more important than depression. Dr. Fränkel's method of employing digitalis hypodermically, beginning on the third day whenever there is no arterial sclerosis, must not be forgotten.

Mortality of Pneumonia.—Dr. R. C. Cabot, of Boston, said that the records of pneumonia which we have so far do not justify the thought that the disease is not more frequent than it used to be. This question must be studied more carefully. Certainly the records of the Boston City Hospital will not be found to substantiate the claims of exaggerated mortality now so common.

Dr. Cohen, of Philadelphia, said that the most important element in pneumonia treatment is to individualize therapeutic effort. In some cases venesection is of use to reduce the toxemia at the beginning. In others, it is of value to relieve the overloaded right heart. In neither of these cases does it seem advisable to inject saline solution afterward. High temperatures, in Dr. Cohen's experience, seem rather favorable than otherwise. The temperature seems to be an index of the vital reaction, and the patient with 104° F. is much more likely to get better than those running lower temperatures. Veratrum viride undoubtedly does good in many cases of pneumonia, but it is not because it is a heart depressant.

Shock of Pneumonia.—Dr. Wells, in closing the discussion, said that at first there is undoubtedly a reduction of arterial tension in pneumonia. This seems to be a protective reaction on nature's part. It is desirable to maintain it as far as possible. Veratrum viride by accomplishing this protects the patient from the shock of the disease. Dr. Wells does not want to

be misunderstood with regard to the use of opium. When patients are very restless and tossing, opium is employed to quiet them. This prevents them from being harmed by their restlessness. When the blood pressure in pneumonia goes up, the prognosis is decidedly unfavorable.

Serum Intravenously.—Dr. Sailer, in closing the discussion, said that undoubtedly serum may be obtained that will be efficient in pneumonia. His idea is that perhaps it should be injected intravenously so as to reach the lungs less diluted than with the present method of injecting simply under the skin. He expects then to make use of this method in some further cases.

Second Day—June 8th.

symposium on arteriosclerosis.

Pathology of Arteriosclerosis.—Dr. William H. Welch, of Baltimore, dwelt on the fact that enormous atheroma of arteries may be present without any heart disease or even hypertrophy and without any rise of arterial tension. At the same time, there may be none of the usual symptoms of sclerosis. The question is whether the rise in blood pressure precedes arterial sclerosis and causes it or whether it is the consequence of elasticity in the arteries. Traube and Pepper insisted that there was some element present in the circulation which first causes the rise in blood pressure. For the determination of this, it is positively necessary to eliminate all cases of Bright's disease in which, of course, high pressure is present as the result of faulty elimination of the used up material. Dr. Welch suggested that the theory formulated by the Leipzig school of pathology which considers that the circulation in the abdominal viscera is the first and the most important question in the production of arteriosclerosis. Sclerotic changes in the kidney and liver are particularly important in this respect. When, however, the course of the arteries does not show any thickening, the mouths of the vessels in the abdomen may show distinct constriction. This has been to a very limited degree the subject of detailed observation; studies in arteriosclerosis are incomplete and especially do not take in these vessels.

Syphilitic Aortitis.—Syphilis is, in Dr. Welch's opinion, a very prominent cause of changes in the aorta and of atheromatous conditions in other arteries throughout the body. When such changes are present, the direct effect of the syphilis can be traced, and this etiological factor should always be given due consideration. Especially is this important from a therapeutic standpoint, as there is more hope from remedial measures. Dr. Welch believes that the effects from local areas of arterial sclerosis may help in understanding the general process. In a kidney recently obtained at autopsy, there was a double blood supply, one artery going to the upper, the other to the lower part of the kidney. One of these arteries showed marked sclerotic changes. The part of the kidney supplied by this showed typically the granular, wrinkled appearance with marked interstitial changes. The other part of the kidney was practically normal without any degenerative appearance.

Arteriosclerosis and Infectious Disease.—Dr. W. S. Thayer, of Baltimore, said that his attention was especially called to the effect of infectious disease in production of arteriosclerosis by observations made on typhoid fever patients. Nearly one-half of the sufferers from typhoid fever during their convalescence and afterward, showed palpable radial arteries. Sometimes these have only been recognized years after the attack of typhoid fever. Sufferers from other diseases showed the same condition in only about 17 per cent. of the cases. In the autopsy records over one-half the cases of typhoid fever showed aortic changes, many of them of recent origin. Cases of coronary disease were also found. In four cases yellow degeneration of the intima of the heart was noted. These are evidently factors that would enter into the production of arteriosclerosis. In typhoid fever, the blood pressure is higher than normal, and as this continues for weeks there is a definite tendency to the production of degeneration of arteries. If typhoid fever is so prominent, other infectious diseases are also likely to exercise a similar influence, so special studies were made in order to determine this.

Statistics in 4,000 Cases.—An analysis of 4,000 histories very carefully taken by fourth-year students at Johns Hopkins Medical School shows that hard work is the most important factor in the production of arteriosclerosis, both as regards the number of cases and the youth of the patients suffering from the affection. After hard work comes the abuse of alcohol. After alcohol, the infectious diseases by the changes which they produce in arteries, give a basis for sclerotic arterial degeneration. Among the infectious diseases, the most important is rheumatism and next after this comes typhoid fever. Scarlet fever also has a definite effect in this direction.

Syphilis and Arteriosclerosis.—Dr. C. Travis Drennen, of Hot Springs, Ark., said that undoubtedly there is a connection between arteriosclerosis and syphilis, but whether syphilis is a direct cause or not cannot be said as yet to be absolutely determined. Dr. Drennen believes that the routine methods of treating syphilis by mercury have been responsible to some extent for the production of arterial sclerosis. The toxins of syphilis act upon the arteries, but so also does mercury, as any other metallic poison that may happen to be present in the system. At a time then, when the presence of syphilis is already causing irritative changes in the arteries, the abuse of mercury is likely to be especially serious. Every physician must have the experience of having patients come into this office who announce that for years on their own responsibility they have been taking without intermission a certain amount of mercury. It would seem then that individualization of the treatment of syphilis is extremely important, lest more harm than good be done.

Arteriosclerosis and Nephritis.—Dr. George Dock, of Ann Arbor, Mich., said that formerly it was the custom to attribute arterial sclerosis to nephritis as the cause. Now, there has come the definite doctrine, more and more widely accepted, that arteriosclerosis may affect the kidney before any inflammatory changes are found in that organ. The lesion of the blood vessels would seem to be a result of a primary set of changes. Undoubtedly infectious diseases produce an effect upon the kidney which may subsequently lead to degeneration of the arteries first within the organs, and later outside. Just what causes arteriosclerosis we do not know and there is an assumption of knowledge in his matter that is to be deprecated. At the present time the studies in blood pressure promise to be of more service than any other form of observation. Undoubtedly hypertension is the most important causative factor of the condition.

Lead and Arteriosclerosis.—Dr. Frank Billings, of Chicago, said that lead poisoning is much more common than is usually thought and in certain of its latent forms may readily escape notice. The metal very readily gains an entrance into the system. Its almost universal use in the arts gives rise to frequent opportunities. A recent case seen at Cook County Hospital il-

lustrates how small an opportunity may be present for absorption of lead and yet lead poisoning ensue. The patient was a laborer in the stock yards who came suffering from typical lead palsy with drop wrist. There seemed to be no possible reason in his occupation for this poisoning. Very careful inquiry, however, elicited the fact that he handled bars of solder. This was absolutely the only lead with which he came in contact, yet it proved sufficient to give him lead poisoning. A second typical case was that of a woman who presented, besides other signs of lead poisoning, the characteristic blue line on the gums. Her husband was a painter, and her only connection with lead was in the washing of her husband's clothes. Shoemakers have been known to acquire lead poisoning as the result of keeping the tin tacks sometimes used in shoes in their mouths. Cigarmakers, who are susceptible, have been known to receive their lead poisoning as a result of rolling the cigars on tin plates. Diamond cutters acquire the disease because precious stones are imbedded in lead when about to be cut, and the slight amount of the metal which thus gets on their hands proves sufficient to produce lead poisoning. In some people, even the slightest handling of the metal soon produces toxic symptoms.

Degenerations.—There is now a well marked degeneration of red cells which is believed to be due to the presence of lead in the system. The red cells have also been found to be carriers of the metal. Whether it is through them that the arteries are affected or because the nervous system early comes under the influence of the metal and causes the rise of blood pressure is not known. The characteristic lesion of the arteries is a proliferative change with hyaline degeneration in patches. This leads ultimately to a thickening of the media with degeneration of the muscular coat. The changes are noted especially in the blood vessels of the abdomen and in the heart, lungs, liver and kidney. The kidney is the most affected organ. There is first a parenchymatous nephritis which is followed later by contraction with interstitial change. The diagnosis of lead poisoning and arteriosclerosis therefrom can only be made by exclusion. It may be said at once that the acute symptoms of lead poisoning, the blue line on the gums and the drop-wrist, are not important for the diagnosis of arteriosclerosis since this is a chronic change, and the acute symptoms often lead to the early abandonment of the occupation in which the lead finds its entrance into the system.

Alcoholism and Arteriosclerosis.—Dr. Richard C. Cabot, of Boston, said that there is a universal consensus in literature that alcohol is the most prominent factor in the production of arteriosclerosis. All the text-books of general medicine, and especially the text-books on heart and arterial disease agree in this, yet there are some skeptics. The two important questions are: What is alcoholism, and what is arteriosclerosis? As regards the latter question, Dr. Cabot believes that all cases should be excluded in which the radial artery is merely palpable, but not tortuous nor stiffened. At the Massachusetts General Hospital, a number of autopsies on patients with palpable arteries in Dr. Wright's hands did not show the presence of any changes that could be called arteriosclerosis. Alcoholism will surely be considered to be present in extreme cases where patients for long years have taken large amounts of intoxicating material. At various institutions in the State of Massachusetts where chronic alcoholics are taken, Dr. Cabot has secured the results of autopsies. Many of these individuals have taken a quart of liquor a day or confessed to forty whiskies with as many "chasers." There is no doubt of alcoholism in these cases. About fifty were excluded because of the evident presence of syphilis. In only 18 out of nearly 300 cases, that is in about 6 per cent., was there arteriosclerosis of the peripheral vessels. Of course, all patients were excluded who were over fifty years of age. If, besides the patients over forty years of age were excluded, there were only four cases or only 2 per cent. of arteriosclerosis in confessed alcoholic cases.

Arteriosclerosis Under Forty-five Years.—In what may be considered premature degeneration of arteries, that is, in men under forty-five years, Dr. Cabot had the opportunity to study 45 cases. In only six of these was there a history of alcoholism. Out of 132 autopsies at the Massachusetts General Hospital, due to arteriosclerosis, 19 cases were in patients under fifty years. Two of these were manifestly syphilitic. Of the remaining 17, only two had a history of alcoholism. In a patient who for ten years had been known to take whisky very liberally, so that a quart a day seemed a small amount, and his family thought that for ten years he had taken this much, no arteriosclerotic changes could be found. Arteriosclerosis seems to be the result of prolonged mental or physical strain much more than to the abuse of alcohol.

(To be Continued.)

SECTION ON SURGERY AND ANATOMY.

FIRST DAY—JUNE 7TH.

The Chairman's address was delivered by Dr. Charles A. Powers, of Denver. It was a forecast of the future as well as a retrospect of the past. He said that two, or at best three centuries ago a man who removed another's viscera and disposed of diseased areas and returned them thus curing the patient, would have done well had he escaped death at the stake.

Growing Importance of Surgery.—This branch of medicine with its many dependent departments has become the most astute science in the world. It calls therefore for the employment of the keenest intellects among our young men and women. This has only recently come to pass. Indeed, it dates from the dawn of the antiseptic era. Prior to that, however, a great deal of magnificent work was done and the surgeon of to-day should not fail to consult old authors who spent a great deal of time and thought in establishing differential diagnosis, which to-day, because of the decreased danger of exploratory incisions, are, it is to be regretted, not so keenly studied as they should be.

Gradual Development and Rise of Surgery.—A century ago the ablest men went into the priesthood. In time the law received an equal proportion of this element. In most recent days medicine is claiming her share, the priesthood is receiving a poorer element; the brains of the country are pretty evenly divided between the lawyer and the physician.

Personal Characteristics of the Surgeon.—Destined to carry responsibilities far greater than those of any other individual, the surgeon must be a man of the very finest mold, both mentally and morally. He must be a man of power and influence. His judicial, as well as his scientific abilities must be cultivated, for he is called to judge cases when life hangs in the balance. The surgeon and the scientific man of medicine are receiving at length their proper recognition. The great captains of industry are beginning to understand what a debt of gratitude the community owes the surgeon, and as a result they are establishing institutes which shall enable the prophylaxis of the public health and other problems of a like nature to be thoroughly worked out in the near future.

Danger in Moles and Warts.—Dr. W. W. Keen, of Philadelphia, gave the histories of 19 of these cases

which had come under his personal observation, and cited six others. He said that it must be understood that a very small percentage of moles, warts and nevi actually undergo malignant change, but on account of our present ignorance of these matters we are unable to forecast their future. Whoever has a scab upon him, will rub that scab off. Thus the patient is often to blame for the production of malignancy because continued traumata lead to malignancy. Any tumor which is constantly irritated is prone to become malignant. A certain sign of malignancy is increase in size. It is held by some pathologists that these three types of tumors degenerate invariably into epitheliomata. This, however, is not true, for sarcomatosis is not uncommon, especially in the case of pigmented moles. The only rational and safe treatment for these cases is early and complete ablation with the knife. It should be done during the harmless stage quite irrespective of the position in which the growth may be. He said he could not urge too strongly upon the profession the necessity of teaching the laity the importance of this sadly neglected subject.

In discussing Dr. Keen's paper Dr. W. L. Rodman, of Philadelphia, said that these lesions were fraught with the utmost danger to human life. The importance of disseminating this knowledge throughout the land could not be overestimated. He said that pigmented moles are the tumors which result in sarcomatosis while the other forms develop into epitheliomata.

Dr. Gustav Fütterer, of Chicago, described a form of epithelial metaplasia, examples of which he had seen in the stomachs of some of the lower mammalia, particularly in those in which the teeth being absent the stomach is obliged to do a very great deal of work in digesting, and as a result suffered more or less frequent traumatism.

Dr. Robert F. Weir, of New York, said that moles, nevi and warts should be looked upon as tumors. He advised the use of monochloracetic acid, stating that patients will often submit to the use of this when they will positively refuse to allow the surgeon to remove the growth with a knife.

Dr. A. D. Bevan, of Chicago, said that there was a possibility that the actual removal of the growth might be the cause not alone of disseminating malignant cells if they had developed at the time of operation, but also possibly drop the balance in certain cases in favor of malignant degeneration. The Pacquelin cautery should be applied to every suspicious case which should afterwards be removed with the knife. Large numbers of people, however, are blessed with a multiplicity of moles or even warts. It is therefore not always practical, if indeed it be wise, to remove them without careful consideration.

Dr. Keen, in closing, said that he had urged the removal of these tumors in as pressing a manner as he did because their danger had been brought home to him by the untimely death of a number of close friends through this preventable cause. He did not deny that common sense must dictate in this as in all other things the treatment of these cutaneous lesions, but the knowledge of their potential danger could not be too broadly known.

Starvation for Malignant Growths.—Dr. R. H. M. Dawbarn, of New York, gave a brief description of the technic of external carotid extirpation. He cited the character and the number of the anastomosis about the face and within the brain and dilated upon the bearing of these anatomical points on the operation of starving the growth. His 60 cases have shown that in the absence of complications a 5 per cent. mortality is to be expected.

Success is to be expected in sarcoma, which, as is well known, spreads by the blood vessels whereas carcinoma spreads by the lymph channels. He spoke of the desirability of tying the inferior dental and mylohyoid artery and resecting the mylohyoid nerve; this latter technic being employed as a safeguard against pain in case of recurrence. Surgeons who propose doing this operation must study the variations in the vessels of the neck and an exploratory incision should always be done to determine whether the internal carotid may not have taken, as it occasionally does, the part of the external carotid and give off important but irregular branches.

Use of Paraffin Injection.—This material combined with vaseline and introduced at a temperature of 120° F. is a convenient medium for stopping the terminal branches of the external carotid. The occipital instead of these branches, should occasionally be plugged but never both. Decision on this point is reached by considering the position of the tumor.

Dr. A. T. Bristow, of Brooklyn, said that he had performed the operation 11 times on six patients. Five were epitheliomata, the other a sarcoma. The immediate result of the operation was to relieve pain and to stop all discharge. This naturally does away with the morphine habit of which the sufferers are usually the victims. It also, even in carcinoma, causes immediate shrinkage of the growth. None of his cases had lived over a year, but they had survived in comfort and died in peace.

Dr. Dawbarn, in closing, said that Dr. Da Costa considered the operation of very great use as a possible means of bringing inoperable cases to the operating table for complete removal. It had been his good fortune to have such a case, and the man was now apparently cured.

Tumors of the Breast After the Menopause.—Dr. J. C. Stewart, of Minneapolis, said that transition of cysto-adenomata to malignant growths was not uncommon. He could therefore not understand how a prominent surgeon had recently recommended that general practitioners should aspirate all these cysts. That there is the very greatest danger of establishing general carcinomatosis by any form of unguarded exploratory incision or puncture, there can be no doubt. In women over forty years the breast is useless, and inasmuch as direct incision is dangerous, the easiest means of making what may be called an indirect exploration is to place an incision in the line which can be used for complete removal, and then to clamp all lymphatics and blood supply. He concluded that tumors of the breast should be regarded malignant until they are proven to be benign.

Dr. William Jepson, of Denver, said that we knew very little of the differential diagnosis of those growths on the borderland between the good and the bad. Cyst formation does not give prognostic indications of any value. Eighty-two per cent. of all tumors of the breast are carcinomata. A small percentage are sarcomata. Less than 10 per cent. are benign. In view of these figures, is differential diagnosis necessary?

Dr. J. C. Bloodgood, of Baltimore, stated that the proportion of malignant growths operated on is decreasing in favor of the benign forms. The reason for this is that more tumors are operated on than formerly. At least 33 per cent. of all tumors are benign. It is interesting where this factor of diminished malignancy, brought about by early operation, will bring us as time goes on. The laity must be instructed that all breast tumors are malignant and should be removed. He concluded that the only type of tumors which do not call for removal are multiple growths in patients under thirty years. In 28 cases of doubtful type in which exploratory incision was practised, but three patients have died.

Dr. Stewart, in closing, said that the conclusion of the matter was that the microscopical examination of a

tumor is sufficient. The question of the character of the exploratory incision is shown by Dr. Bloodgood's observations to be merely of academic interest.

Pathology of the Knee-joint.—Dr. A. Hoffa, of Berlin, Germany, said that papillomatosis has nothing to do with tuberculosis. He described a form of lipofibromata, a large number of which he has removed from joints. In the first case, he operated for what he thought was a displaced cartilage. A section of these fatty tumors shows a reticulum filled with endothelial cells and small amounts of fat. They are but slightly vascular. This tissue is apt to grow after moderate trauma of the joint and hemorrhages into the tumors may cause them to simulate floating cartilage very closely.

Surgical Lesions of the Axillary Plexus.—Dr. John A. Wyeth, of New York, reported a case in which no nerve trunks have been severed but in which a total paralysis of sensation and motion resulted from pressure. Section of the axilla had been made and the arm was hyperextended. He cited five cases of neuromata of the axilla and suggested that in the event of the surgeon being unable to remove them, an admirable technic might be to sever the clavicle, as he had done on one occasion, allowing it to unite with an upward angle so as to give the part more room. In his case the patient was granted three years of comfort by this method.

Dr. J. B. Murphy, of Chicago, said that the position of the arm during operation is most important. Fortunately musculospinal paralysis which is caused by allowing the arm to hang over the side of the table is rare. These paralyses, he said, are not always curable.

Matas' Operation for Popliteal Aneurism.—Dr. J. F. Binnie, of Kansas City, said that this excellent technic could be used for fusiform or for saculated aneurisms. He described the technic which he had used and reported the case in full. It was one showing marked atheroma and the aneurism measured six by four inches. Although the case suppurated, it went on to an admirable recovery.

Dr. R. Matas, of New Orleans, said that the technic was easy and that its elastic pliability made it more valuable than a positively fixed method. The points which he considered important were: Free exposure of sac, early control of all vascular openings of sac. Tier suture obliterating the walls. Restoration of lumen is often possible. Dr. Matas reported histories of six cases. This, he said, was not a large number, but the occasion for using the technic does not often occur. It is most fortunate, in the opinion of Matas, that a wide attention is being given to the operation, because it seems unquestionably to be a life-giving one.

Dr. J. B. Murphy, of Chicago, described a fatal case in which he had endeavored with apparent success to use a modification of Mayo's flap method of closing the sac. He regards infection in and about blood vessels as more dangerous than occurring anywhere else.

SECOND DAY—JUNE 8TH.

Twine in Lieu of the Elastic Ligature for Performing Gastro-enterostomy.—Dr. J. W. Draper Maury, of New York, reviewed the history of the experimental work which has recently been done at the surgical laboratory of Columbia University, and described the evolution of a twine triangular stitch. He said that it was a modification of McGraw's method, but that by the use of twine instead of elastic the technic was made available for all occasions in which it might be suitably employed. The elastic, he said, as is well known, is prone to degenerate from contact with the air. Twine is to be had anywhere, the ordinary commercial white grade too strong to be broken by the hands, serving the purpose admirably. He had brought to the meeting and demonstrated thirteen specimens of dogs' stomach and intestines which had been perforated by the twine. Two of these were recent, having been removed but a day or so ago, and they had been cut out in something less than 3½ days. He described the technic of introducing the ligature and gave a practical demonstration of it before the section.

Remarks on the Disadvantages of the Murphy Button.—Dr. Robert F. Weir, of New York, first paid a very graceful tribute to the originator of this device which, he said, had more than any other contributed to the development of the subject of abdominal surgery. One of the advantages claimed for the button consisted in the rapidity of its introduction. A wide experience has, however, proven that safety sutures are indispensable. This therefore diminishes the advantage and places the mechanism in the category of other well known technics. A disadvantage of the instrument has always been and will continue to be that makers refuse to follow the explicit directions of Murphy. Unless these be most faithfully executed, there is certain to be grave danger for the patient and disappointment for the surgeon. Weir has done gastro-enterostomy with the button seventy times. He perfected a flange to prevent it from falling into the stomach, but in the one case in which this accident befell him it proved to be the button with the flange. On the last thirty patients he has performed entero-enterostomy, and this has done away with the vicious cycle. He said that a further disadvantage with the button lay in the fact that 58 per cent. of them are not recovered, they either remaining in a fold of the colon or else being passed and lost. He said that in future he would perform gastro-enterostomy either by the Weir-Maury method of using a triangularly inserted twine, or by employing a technic which he has recently used in five cases. This consists in tying the entero-enterostomy button with a stout silk linen fish line under no tension to the entero-enterostomy button above. A small bit of twine is left to hang down into the gut from the entero-enterostomy to serve as an excitant for peristalsis. The results have been most encouraging.

Excision of the Ulcer Bearing Area in Gastric Ulcer.—Dr. W. L. Rodman, of Philadelphia, said that this technic could not be employed in any but chosen cases. In a certain proportion of gastric lesions, however, it was obviously the only surgical procedure. He described in full the technic of his method of pyloroplasty which includes the use of the Doyen clamp and the removal of the first portion of the duodenum. He said that 25 per cent. to 50 per cent. of all cases were healed by medical means. Those which are most apt to come to the surgeon are of the type found in the male who is past forty years of age. Gastro-enterostomy has failed in at least six per cent. of cases to control hemorrhage from an acute ulcer. Furthermore, it does not remove the cicatrix of the old wound, which, as is well known, is very prone to undergo degeneration.

Necessity of Drainage.—This is a *sine qua non* here more to be urged perhaps in this operation than in any other on the stomach, because of its eliminating all danger of malignant degeneration. Duodenal ulcers usually accompany or are accompanied by ulcers of the stomach. Ulcers usually are multiple contrary to the old teaching, and it is not uncommon that they occur directly on opposite surfaces of the stomach, one evidently having produced the other.

Dr. A. J. Ochsner, of Chicago, reported the histories of 86 patients on whom he had recently operated by the McGraw technic. Three of these had died, but they might fairly be considered inoperable cases. They certainly were patients upon whom he never would have even considered operation with any other technic. He

had done the operation of cholecystenterostomy upon one patient and stated that the technic was far from satisfactory for this operation. The difference in density between the two viscera prevents satisfactory manipulation. Absence of shock was very marked and is probably to be explained by the fact that there is so little manipulation. This factor undoubtedly serves also to explain much of the success of the Murphy button.

Dr. William J. Mayo expressed himself as delighted with Weir's method of tying the buttons together. He asked what would be the result if the pull of the lower button proved inadequate and the gastric button fell into the stomach? Truly there would then be a dilemma, for the string would straddle the fistula. He advised the suture operation on the posterior surface of the stomach, saying that it could be done in from 12 to 17 minutes. He felt assured that Rodman's operation is based on ideal surgical principles, but felt equally certain that it could not be carried out in all cases. Pylorectomy and partial resection of the duodenum was, in his opinion, a fairly formidable operation to suggest for the cure of an ulcerated stomach. He reiterated his belief that the vicious cycle is due to particles of food being driven out into the loop through the patent pylorus by the muscular action of the stomach.

Dr. J. B. Murphy said that the button had many more defects than had been enumerated by Dr. Weir. He admitted freely that it occasionally fell into the stomach, one of the buttons modified by Weir having disappointed him in this way at a recent date. He agreed with Dr. Ochsner that there must be the least possible manipulation of the viscera. He pointed out a very important anatomical relation. When endeavoring to place an anastomosis at the lowest point of the stomach, it must be borne in mind that the organ when dilatation begins is pressed down from above so that the cardia may often be seen one inch below the pylorus. If account of this be not taken at the time of operation, the opening will be made at a point too far to the left, and when on account of drainage, the stomach resumes its normal position, which it will, the opening is found to be too near the cardia. He said that in his opinion, Mayo was absolutely right in contending that the pylorus of each one of the cases of gastro-enterostomy should be permanently sealed, but he had not as yet found any satisfactory method for effecting this.

Dr. R. H. M. Dawbarn stated that he had for years been in the habit of using a cork instead of a faucet as a means of handling the buttons. This plug serves a double purpose in that, first, it blocks the canal and prevents possible contamination, and second, if the button should happen to drop back into the gut, as it sometimes does, the shape of the cork will not allow it to actually enter the viscus.

Gastro-enterostomy by Crushing.—Dr. L. L. McArthur, of Chicago, showed two very interesting specimens. They represented attempts to effect gastro-enterostomy by means of crushing opposing areas of the viscera and then joining them together with Lembert stitches. Finding that this technic failed, no matter how entirely crushed the gut might be, he had endeavored to complete the necrosis by tying off the blood supply with a purse string suture. This had also failed. He wished these attempts registered in order that they might prevent other experimenters from wasting time in like endeavors. One of his specimens showed very beautifully that the Lembert stitches which are placed on the outer surface of the gut eventually pass through and are extruded into the lumen.

Dr. A. A. Berg, of New York, said that due credit ought to be given in all this work to Gaston who had originally devised the technic.

Dr. S. Lloyd, of New York, criticized the twine freely. He said that if the elastic be known to work well, why look for a substitute? He stated further that the elastic begins to cut through before the twine and that the elastic is much the more readily sterilized.

Dr. W. L. Rodman, of Philadelphia, in closing said in answer to the criticism that pylororectomy was too severe an operation for the relief of ulcer and that the mortality was 30 per cent., and further that it took an undue amount of time to accomplish the technic; that the mortality in his opinion did not exceed 10 per cent. in suitably chosen cases; that the work could be done within a reasonably short time and that the great advantage of the operation lay in the fact that after it there could be no chance of malignant degeneration. No man, he said, however skilful could possibly say on inspection whether a given tumor situated in the stomach, the patient presenting which had given a history of ulcer, was or was not malignant. Medical history was full of cases which had been operated on by such men as Keen in which the patient had, after a most lamentable prognosis gone on to a speedy and permanent recovery.

Dr. Maury, in closing, said that he was not aware that Dr. Lloyd was in possession of data bearing on the relative rate at which the twine and the ligature would begin to cut their respective fistulæ. Furthermore, that he had not heard of twine being injured by boiling and that its sterilization was as easy, if not simpler, than that of the elastic. In answer to the remark that twine had been discussed as a substitute for the elastic at the New York Academy of Medicine during the past winter, he called attention to the fact that he suggested the use of twine for this purpose in a communication in the Medical News of September 12, 1903, which antedated the meetings of the Academy. In discussing Dr. Ochsner's use of the ligature to produce an opening after he had resected the greater portion of the stomach and closed the small remnant of the viscus, Dr. Maury said that it was interesting to observe that if the pylorus in dogs were sealed and the stitch put in at the same time, the dogs would die within thirty-six hours, of symptoms resembling tetany. Whether the human being was less liable to this toxemia or whether Dr. Ochsner's success was due to the fact that he had removed a large portion of the stomach which is thought to secrete the toxic substances, was difficult to say.

Rupture of Mesenteric Glands During Typhoid Simulating Intestinal Perforation.—Dr. R. G. Le Conte, of Philadelphia, said that this complication is a rare one. There are from 130 to 250 glands in the ileum. These are divided into three distinct groups, the second group, which is located at the mesentery is the one involved in this discussion. The lesion is a diffuse one and seemingly has no bearing of a direct nature on the typhoid germ. The pathological etiology is most obscure. He concluded that whatever the cause, there are always enlargement and softening. When this process extends to the blood supply of the glandular capsule, there are apt to be a destruction of this membrane and pouring out of infection into the peritoneal cavity. Although 600 cases of typhoid are treated annually at the Pennsylvania Hospital, this is the first case to be reported from that institution. If the source of infection does not come from the lumen of the gut, it seems most likely to take its origin in endothelial proliferation followed perhaps by thrombosis of the blood supply or by actual infection of the gland by the ordinary pus-producing bacteria.

Intestinal Anastomosis by a New Method.—Dr. J. S. Horsley, of Richmond, Va., described in a beautifully illustrated article a method of intestinal anastomosis which he believed to have certain points of unusual merit. The technic is of the through and through variety and was shown to be simple and efficacious by a study of the charts. He cited a fatal case and exhibited a specimen of perfect union which had been obtained at the autopsy.

Dr. Connell endorsed this suture because it was of the through and through variety. He said that no other form of stitch could have the strength of this type.

Retroperitoneal Myxolipoma.—Dr. George Ben Johnson, of Richmond, Va., said that these little known tumors were divided into three classes, (1) perirenal; (2) doubtful; (3) mesenteric. There are 48 cases in the literature. These tumors are 30 per cent. more common in women than in men. Further than this nothing is known as to their cause. The diagnosis is almost impossible because of their cystic character. A pathological report of the tumor was read.

Drainage of the Biliary Tract.—Dr. Maurice H. Richardson, of Boston, said that he regarded immediate closure of a biliary wound as absolutely contraindicated. Fistula operations are extremely dangerous. Stones are often found in the course of operations for other conditions, the existence of which has never been suspected. Very many inexplicable and unusual symptoms may be safely ascribed to gall-stones. He concluded (1) That stones when they are known to exist, if local conditions are not unfavorable, should be removed at once whether causing symptoms or not. (2) Drainage should be maintained until the bile ceases to flow. (3) An incision similar to the "gridiron" for appendicitis should be used in these operations. (4) A permanent fistula usually means an overlooked stone in the common duct.

Gall-stones in the Common Duct.—Archibald MacLaren, of St. Paul, said that gall-stones are usually to be found associated with chronic lesions of the mucous membrane of the gall-bladder. Since the mid part of the duct is the most readily dilated, stones naturally find lodgment there. In one to five or one to seven of all cases of cholelithiasis stones are lodged in the common duct. Surgically considered the gall-bladder very closely resembles the appendix and this is one reason for treating these two organs similarly. All stones should be taken out as soon as they are diagnosed because nothing is known or can be foretold of the future of the stone.

Dr. J. D. Bryant, of New York, agreed in the fullest detail with Dr. Richardson, particularly as to drainage. He said that the proliferative changes in the mucous membrane of the bile ducts must block them and that all effort should be made to take away the chance of any pressure existing in addition to the factor already mentioned.

Dr. W. J. Mayo said that the time was approaching when the general practitioner would be as eager to have gall-stones operated on early, now that his training is complete, as he is to have an appendix taken out. He said that there were certain definite indications for cholecystectomy, viz., in an already obliterated organ and in certain mild forms of cholecystitis, when nature has already indicated the non-usefulness of the organ.

Appendicitis in Children.—Dr. A. J. McCosh, of New York, said that the disease in children differs very widely and in certain various specific details from its characteristic appearance in adults. One has practically to depend for diagnosis in children upon the occurrence of persistent vomiting in the absence of food. Pain, because of the characteristic vagaries of a child, is of little or no value. The leucocyte count has been stated on very high authority to be valueless in the diagnosis of appendicitis in children. The differential diagnosis has to be made from gastro-enteritis, from basal pneumona, and from diaphragmatic pleurisy. The Author stated unconditionally that upon the testimony of persistent vomiting alone in suitably chosen cases, diagnosis for appendicitis could be reached, the symptom alone being enough to justify immediate operation. He gave a large number of statistics showing the frequency of appendicitis in children, basing his statistics upon his last thousand cases. Over 50 per cent. had occurred between the ages of 20 and 35 years, after which period the occurrence of appendicitis becomes rapidly less. Before ten years of age 7 per cent. of his patients had had appendicitis, while his youngest patient had been a babe of twelve months.

Diagnosis of Appendicitis.—Should the appendix be removed as a side issue? was discussed by Dr. F. W. McRae, of Atlanta, who based his query upon 270 cases. Twenty-five per cent. of these had been marked by obscure conditions which had a more or less direct bearing upon his mortality statistics. Endeavoring, however, to give suitable weight to this factor, he had reached the conclusion that in uncomplicated cases it was the part of wisdom to remove the appendix irrespective of its condition. This was based partly upon the ease and apparent freedom from danger of the operation, and partly upon the fact that it is almost impossible to recognize a diseased appendix with the naked eye while it is quiescent. He devoted considerable attention to a consideration of the controversy as to whether the bound down and adherent appendix should be left alone or should be excised. He said that a failure to remove the appendix is frequently followed by a necessity to excise it shortly after; this brings pain to the patient and discredit to the operator. Removal advised when operating for floating kidney, for gall-bladder and rectal troubles.

Factors in the Mortality of Appendicitis.—Dr. J. B. Deaver, of Philadelphia, said that the palpating hand of the surgeon should be the only agent used in determining whether or not to operate in a given case of appendicitis. He said that there were three causes of delay. The first was brought about by the period of latency of the disease. The second by the delay of the patient in calling his physician, and third by the delay of the physician himself in establishing a diagnosis and operating. He spoke of the appalling danger of using opiates for any form of bellyache, especially in children. He lamented that much of the old time delicacy of touch and interpretation of obscure conditions had been lost by the introduction of mechanical and laboratory means of reaching diagnosis. He reiterated the well-known belief that leucocytosis is utterly useless because, with its establishment in too many cases, the time for operation is past. Pus cases are protected by nature in three ways, by adhesions and by specific protective bodies and by dilution. Adhesions are often of limited value as a means of walling off infection and frequently fail to limit its spread. The development of antitoxins was little recognized though potent. A dilution of the infection by serum which results directly from the inflammatory reaction is an important protective mechanism. He stated that in his belief much could be learned from observing the condition of the patient while going under ether. Other things being equal, those patients who took ether badly were apt to be more seriously sick than those who took it well.

Abdominal Drainage.—It is criminal, he thought, to remove gauze within forty-eight to seventy-two hours.

It should be left for at least eight days. The cigarette drains, so much used in New York, may well be likened to a sort of kindergarten method of getting pus out of the belly. He strongly urged and insisted upon the use of Fowler's position in the postoperative treatment of peritonitis.

Dr. E. LaPlace, of Philadelphia, said that in every case in which the patient died of appendicitis some one had been guilty of allowing the prime moment to pass unheeded. He agreed in every other detail with Dr. Deaver.

Dr. A. J. Ochsner said that children should be operated on early, and if not operated upon they should at least be put in Fowler's position. He agreed with Deaver in all the various classes of appendicular involvement except one, and he felt sure that inside of five years Deaver would come to his way of thinking. He quoted from one thousand cases upon each one of which he had operated upon at the Augustana Hospital, stating that including the cases of circumscribed peritonitis, his mortality had been but 2.2 per cent.

Dr. J. B. Murphy, of Chicago, said that he had learned to dread the subsidence of symptoms. He cited 16 cases of perforative peritonitis, which he had treated with but one death. Pus in the peritoneum, as elsewhere, is prone to absorb. This is the logical reason for simply cutting a hole and relieving the pressure. On the principle that handling is bad, there should be no washing and no manipulation of any sort.

Dr. Robert T. Morris, of New York, said that in answer to the accusation that the cigarette drains were suitable for the kindergarten practice of surgery, he would advise his friend from Philadelphia not to practise taxidermy upon his patient.

(To be Continued.)

SECTION OF OBSTETRICS AND DISEASES OF WOMEN.

First Day—June 7, 1904.

Chairman's Address—Last Year's Progress in Gynecology. Senile Endometritis.—Dr. L. H. Dunning, of Indianapolis, after a brief discussion of what had been accomplished during the last year, considered the subject mentioned as the title of his paper. He expressed the belief that this complaint should be put in a class by itself. These cases were not as uncommon as ordinarily believed, as from his own experience he found that about three per cent. of the patients in his practice presented this condition. There were two varieties of the disease, the acute and the chronic. Of the former he reported a case in a woman of fifty-four years, who presented a mixed infection, one element of which was gonorrhea. The process rapidly spread to the surrounding tissues and in such cases may be sufficiently severe to demand complete hysterectomy. The chronic forms may also call for radical treatment, and he reported on the pathology of those conditions which closely resembled either carcinoma or adenoma of the cervix. The usual treatment advocated by Dr. Dunning was gradual dilatation with the tent and curettage. It is also necessary to thoroughly cure the vaginitis.

Carcinoma of the Uterine Cervix and Surrounding Tissues.—Dr. J. A. Sampson, of Baltimore, called attention to the high percentage of recurrences which followed the operative treatment for cancer of the cervix and claimed that this was sufficient evidence for the assumption that the growth had invaded the surrounding tissues at the time of the operation and that hysterectomy alone cured the disease in but a small proportion of cases. A study of the anatomical relations between the cervix and the neighboring parts showed that this relation is varied by the position of the uterus in the pelvis and that the growth did not have to extend far anteriorly in order to involve the bladder, or laterally to reach or extend beyond the ureters. A study of the specimens obtained from the more radical operative cases demonstrated how the above takes place and emphasized the importance of a wide excision of the primary growth. The only hope of bettering the results, he believed, lay in an early diagnosis, and in these early cases doing the most radical operation possible. This would afford the best chance for a cure.

Electrothermic Clamps.—Dr. C. P. Noble, of Philadelphia, presented a critical analysis of the results secured by the use of the electrothermic clamps in the treatment of cancer of the uterus, and referred to the various accidents arising from the employment of the method. The nine cases which the writer reported were all unfavorable and not suitable to any other method of treatment. There was only one death, and that from secondary hemorrhage as the direct result of the operation. One of the after complications of this operation is the liability to the production of fistulæ between the vagina and the bladder or ureter, which occurred in five of his cases. Two of these had closed, one was about to close and the other two remained open to date. He believed that in the advanced cases the electric clamp offered a very good chance for improving the condition, but considered that early diagnosis was the essential in all forms of treatment.

Primary Chorio-epithelioma Malignum Outside of the Placental Site.—Dr. Palmer Findley, of Chicago, after a general consideration of the subject and a review of the reported cases, presented an instance where the growth was primary in the uterine wall, with metastatic deposits in the vagina. The case reported was the twenty-first known. The woman had not menstruated for three years, then began again, accompanied by pain and vaginal discharge. There was also a menorrhagia. A radical operation was done and recurrences had been noted since the operation four months ago. The prognosis in such cases should always be guarded as no definite opinion can be given as to the degree of the distribution of metastatic deposits. The true nature of the growth should always be determined by pathological examination, as a case which he was about to report at this meeting turned out to be a carcinoma, containing collections of giant cells closely resembling syncytial masses.

The discussion of these three papers was begun by Dr. Wathen, of Louisville, who stated that although he advocated hysterectomy, he was entirely opposed to the extensive removal of the lymphatics as it was impossible to recognize and distinguish all the infected structures and the operation was unnecessarily prolonged.

Dr. G. B. Massey, of Philadelphia, called attention to the possibility of opening up new lymph channels by cutting operations and bringing on in this manner liability to infection from metastatic deposits. He thought cauterization preferable and claimed that a patient could stand 300 milliampères applied to the cervix without anesthesia. He also believed that interrupted applications of the cautery were preferable to a complete operation at one sitting.

Dr. A. L. Smith, of Montreal, said that he did not always find it well to wait for a pathological report but to go ahead and do an operation based on clinical evidence.

Dr. A. H. Cordier, of Kansas City, considered that good results could be had from the use of the thermocautery. The latter avoids the opportunities for infection, which had a marked influence on the rapidity of

later growth. After converting the elevated mass into a conical ulcer, he also applied carbide of calcium with good results.

Dr. J. H. Carstens, of Detroit, quoted from the recent work of Schauta, and insisted that our knowledge of the anatomy of this region was too limited to warrant extensive dissection here. The recurrences were also noted in the surrounding cellular tissue, which could not be removed. Unless the diagnosis had been sufficiently early to have done a vaginal hysterectomy, it was better to leave the case alone.

Dr. A. Goldspohn, of Chicago, said that the recurrences began in the vagina very often; he advocated a wide resection of this, rather than an extensive resection of the pelvic glands. He also claimed that it was safer to remove the uterus through the vagina, after it had been freed from above and the abdominal wall closed.

Others who took part in the discussion were Drs. Downes, Clark, Lawrence, Massey, Sandberg, Carey, Chandler, Humiston, and Theinhaus.

Technic of Wounds Incident to Laparotomy.—Dr. H. O. Marcy, of Boston, in tracing the history of this subject, referred to the modifications resulting from the introduction of antiseptic and aseptic methods. He called attention to the importance of closing as far as possible all peritoneal rents and abrasions, leaving no wounded surfaces within the abdominal cavity uncovered by healthy peritoneum. He described the method now employed by him, in which, after the peritoneum and fascia are sutured with absorbable animal sutures (catgut, kangaroo tendon), the skin wound is closed with a subcuticular suture of gut sufficiently fine to avoid causing infection from the sweat glands. Drainage was reserved for septic cases. In a clean case the wound was covered with iodoform collodion, and a further bandage is only applied when there was much vomiting expected.

The paper was discussed by Drs. Goldspohn, Orton, Longyear, Dorsett, and the Chairman, all of whom paid a high tribute to the value of Dr. Marcy's endeavors to introduce into surgery the employment of absorbable suture material.

The Appendiculo-ovarian Ligament.—Dr. D. H. Craig, of Boston, described the anatomy of this structure as first delineated by Clao and Durand, and called attention to the mechanical effect on the female pelvic organs, when the ligament is in a state of pathologic thickening and contraction. He claimed that the contraction probably very rarely, if ever, produces pure retroversion. He reported six cases personally obseved by himself, in which the diagnosis had been made before operation. The chief symptom of the condition was tenderness along a line extending from McBurney's point to the ovary.

SECOND DAY—JUNE 8TH.

Diagnosis and Treatment of Pelvic Deformity.—Dr. Geo. Boyd, of Philadelphia, referred to the frequency of pelvic deformity in America at the present time. This called attention to the diagnostic value of the pelvimeter, and the necessity for a careful study of the size and position of the fetal ovoid. The several methods of estimating the relative disproportion between the pelvic canal and the fetal body were then gone into. The induction of premature labor would be the ideal procedure, if it were possible to estimate correctly the exact length of gestation. His own experiences in this had been unsatisfactory and he thought it best to let the pregnancy go to term in most cases. Each case, however, must be studied individually. The fetal head is the only trustworthy pelvimeter. In cases of moderate deformity, the test of previous labors was the essential determinative factor. In multiparæ, where there was a history of previous labors with dead born children, Cæsarean section should be undertaken.

Dr. C. S. Bacon, of Chicago, thought that it would not be so difficult to estimate the length of pregnancy, if it were borne in mind that the morning sickness usually dated from the third or fourth week after conception, and the fetal movements from the eighteenth or nineteenth week. He believed that the high mortality in the children was due to lack of proper preparation, rather than to other causes.

Dr. Carey, of Chicago, stated that the prognosis in such cases depended on the size of the head as well as on the size of the pelvis, and also on the degree of ossification present in the fetal skull.

Heart Disease an Obstetric Complication.—Dr. C. S. Bacon, of Chicago, stated that heart disease might be due to pregnancy or labor, *e.g.*, myocarditis due to toxemia of eclampsia, and endocarditis due to puerperal infection. As preexisting heart disease did not interfere with pregnancy, its frequency corresponded to the frequency of the disease. The usual effect of heart disease on pregnancy was to cause abortion, and the effects of pregnancy on heart disease were dyspnea, bronchitis, edema, palpitation, indigestion, etc. Labor might cause sudden death. In the management of these cases, the patient's station in life and whether or not she was acquainted with her condition, determined the induction of labor. He did not think it advisable to await the spontaneous abortion. Where it was determined to carry the pregnancy to full term, the patient should assume the horizontal position as soon as any tendency to uterine contractions appeared. Opium might be given for considerable periods. During the puerperium, infection was particularly likely to occur, especially in the air passages. No nursing should be permitted and treatment should be kept up for at least three months. Among stimulants he believed that oxygen was the most valuable and trustworthy.

Dr. R. W. Holmes, of Chicago, claimed that opium should be stopped as soon as labor began, for he had seen a number of babies affected by the drug thus given. During the third stage he recommended bloodletting, and this could be accomplished by slow manual removal of the placenta. Only the smaller size bags should be used for dilatation, as the larger ones bring about an increase of intra-uterine pressure.

Dr. Carey, of Chicago, protested against the immediate removal of the placenta, as insufficient control of the hemorrhage was secured and too much danger from infection resulted.

Dr. A. O. Hastings, of Toronto, objected to manual extraction of the placenta and believed that better results could be secured from venesection. He had no bad experiences with morphine and considered it most valuable for the dyspnea. As the symptoms were often more alarming at the seventh month than they were later, he cautioned against the too early induction of labor.

Dr. Bacon, in conclusion, said that the patients needed stimulation after labor, especially by oxygen, rather than bloodletting. He also thought that the insufficient placental circulation caused the danger to the child rather than the morphine.

Cæsarean Section in Placenta Previa.—Dr. J. F. Moran, of Washington, discussed this important subject. Cæsarean section had been recommended by some writers during the last ten years, but in 24 operations by 21 operators, the maternal mortality was 20.5 per cent., and the infant mortality 24 per cent. These were all emergency operations and statistics of cases treated by other methods give a slightly lower maternal mortality, but a decidedly greater infant mortality. Present sta-

tistics were insufficient for guidance, but there was undoubtedly a limited field for the operation.

Dr. G. F. Harrison, of New York, considered that Cæsarean section for placenta previa was not a suitable surgical interference and opposed the procedure. He had never seen a case where it had been indicated in preference to other plans of obstetrical treatment.

Dr. F. F. Lawrence, of Columbus, Ohio, favored the procedure in so far as it afforded an absolute means of controlling hemorrhage and sepsis. Pulling down the foot does not control bleeding as uterine inertia is usually present.

Dr. Holmes, of Chicago, claimed that the only cases in which the operation should be done were those with a rigid os or a contracted pelvis. The statistics presented thus far were compiled by gynecologists rather than by obstetricians, and did not present a fair judgment of the subject.

Dr. Dorsey considered that placenta previa was serious enough to warrant the induction of premature labor, but the time when the patient was first seen really determined the course to be pursued.

The Difficulties and Dangers of Accouchement Forcé.—Dr. H. G. Wetherill, of Denver, believed that the present manual methods were dangerous and slow, and that the instrumental methods, in addition, required expensive special apparatus, often unavailable when most needed. For this reason he recommended the employment of graduated sizes of the Sym's duck-bill speculum for the purpose of dilating the cervix. The latter was properly grasped with tenaculæ, and the smaller sizes introduced after sufficient dilatation had been secured with a uterine dilator. A speculum could be held in each hand and stretching secured by a rocking motion. He reported two cases in which the method was successfully used (toxemia, without convulsions, but with retinitis).

Dr. J. H. Carstens, of Detroit, stated that such a method was too slow and he preferred vaginal Cæsarean section in such toxic cases.

Dr. R. W. Holmes, of Chicago, believed that the os was usually too high to permit of the introduction of these specula and that the tenaculæ were liable to tear out. A number of others also spoke against the advisability of the method.

Repair of the Anterior Vaginal Wall after Labor.—Dr. B. C. Hirst, of Philadelphia, read this paper, in which he called attention to the importance of examining all women after delivery in order to detect injuries of the urogenital diaphragm in the anterior wall of the vagina, the urogenital muscle and its fascia. This should be done digitally by preference, and the reader claimed that it was feasible to repair the injury primarily, although it might be submucous. He detailed the best form of operation for a cystocele when developed and considered that it might be safely done within five days after delivery without danger. The report of a large number of cases from the author's operative service followed.

New Operation for Cystocele.—Dr. J. Riddle Goffe, of New York, believed that cystocele in virgins and nulliparæ was usually due to supravaginal elongation of the cervix. This brought about a general descensus of the upper support of the vagina and the anterior vaginal wall, and a consequent prolapse of the bladder. In multiparæ cystocele was a frequent accompaniment of retroposition of the uterus, sometimes descensus and prolapse of that organ. When these conditions did not exist, cystocele partook of the character of a true hernia. He then commented on the inefficiency of previous operations and the reasons for this, as they do not take into account the true anatomical conditions. In the operation which he suggested, the bladder was freed from it attachments through a T-shaped incision in the anterior vaginal wall, and stitched by means of three sutures, to the uterus and the broad ligaments on either side. This avoids a folding of the base of the bladder and the formation of pockets. It also prevents shortening of the anterior wall. He reported eight successful cases.

The discussion on these two papers was combined. Dr. Price, of Philadelphia, insisted that intermediate repair was not good surgery, and was unsafe on account of the septic condition of the vaginal canal. Others who discussed the papers were Drs. Chandler, Stone, Bovée, and Burtenshaw. The latter thought that the broad ligaments were too friable for the attachment of the bladder. Dr. Holmes claimed that a cystocele during the first few days after delivery was a physiological condition, and that time should elapse before any operation be undertaken.

Repair of Pelvic Floor Lacerations.—Dr. J. Hawley Burtenshaw, of New York, pointed out the advantages from immediate repair of lacerations and said that the failure to obtain good results was usually due to lack of appreciation of the pathology. He claimed that few modern operations of secondary perineorrhaphy accomplished what was alleged for them. They reduced the lumen of the canal and partially closed the outlet, but did not restore the floor to the normal. Vaginal sulci might frequently be demonstrated in women without laceration of the levator, and therefore their presence was not pathognomonic of laceration. In order to close muscular rents, their edges must be raw and closely approximated, and held so until united. Most posterior wall surgery did not expose levator ani muscle and fascia, but the muscular wall was partially denuded and backed up against itself, in which position the surfaces united. Nothing more was gained by Emmet's operation than by Hegar's, because denudation in each was superficial. The muscular walls of the vagina should be firmly anchored to the sphincter vaginæ, to other muscular structures at the orifice and to a movable organ, the uterus. The introduction of sutures in the sulci by the Emmet method had a marked tendency to draw the wall downward and thus increased the traction on an already retrodisplaced womb.

Treatment of Complete Uterine and Vaginal Prolapse.—Dr. F. H. Wiggin, of New York, stated that this condition is practically a reducible hernia through the pelvic floor, due primarily to the separation of the tendons of the muscles forming this floor and the consequent formation of a rectocele. The indications for treatment were, the reduction of the hernia, the obliteration of the sac, the repair of the pelvic floor and the removal of redundant tissue on the anterior vaginal wall. In the reader's experience the obliteration of the sac was best accomplished by intra-abdominal support obtained by means of purse-string sutures passed through the body of the uterus and broad ligaments on either side.

Multiple Abscesses of the Omentum Following Grave Septic Peritonitis.—Dr. H. O. Pantzer, of Indianapolis, read this paper and reported two cases.

(To be Continued.)

SECTION ON PEDIATRICS.

First Day—June 7th.

The first session was called to order on Tuesday, June 7, at 2.30 P.M., with Dr. Charles G. Kerley, of New York, presiding.

The Chairman's Address: The Demands of the Child by Virtue of Right.—After extending a wel-

come to the members and guests, Dr. Kerley gave some of his impressions and thoughts which were the result of sixteen years' observation of children. He emphasized the importance which is given to the care of domestic animals, the mother is nourished and kept under conditions favorable to the production of a healthy offspring and the young animal is even more carefully fostered. Only by so doing may the highest type be produced. This principle is recognized by the National Department of Agriculture, which makes practical application of these facts in the rearing of domestic animals. The physician should realize the still greater importance of the necessity of his supervision of the conditions surrounding the unborn child and of the proper nourishment, cleanliness and environment generally of the growing child. Each year should produce its proper growth. Lost or retarded growth could never be made up in a later year and always showed in maturity. Instincts in animals tells them what they shall eat. It tells man nothing, but he may be taught, and the physician must do this. In a series of observation among children of the laboring classes of New York, only twenty per cent. were found normally developed. The large percentage of the poorly developed was due not to insufficient food but to the wrong kind of food. Early management therefore and particularly early nutrition of the child become of the greatest importance to the State, and education of mothers in all that conduces to the production of healthy children is our public duty as physicians. One reason why country children are generally stronger than city children lies in the fact that country mothers more frequently prepare the food while the city mother depends upon food already prepared. Heredity is an important factor in the development of the child, but nutrition and cleanliness are of far greater importance. Many vocations now require a physical examination to prove the elegibility of the adult and the public has a right to demand this, but the child also has an equal right to a proper preparation for this condition. From the lack of this proper physical preparation of the child, criminals, degenerates and weaklings have been produced. A study of children in the New York Children's Court fully demonstrates the truth of this statement. Most of these were found to be underdeveloped, anemic and dirty, while not one-third of them had proper home surroundings. A merchant in New York City had, after physical examination, rejected 240 out of 250 applicants for positions requiring physical strength in young women. The condition of children in England, where 60 per cent. are underfed, is worse than in America, and there is cause for fear of the mental degeneration of children in the future unless the tendency of present conditions is altered. This should be done by governmental prevention of overcrowding and unhealthy conditions, such as are found in our large cities. Since ignorance is the larger cause of the improper conditions surrounding children the physicians who alone are particularly fitted to do so should teach the mother how to properly rear her children. It seems that the future of the United States depends upon the doctors more than upon any other calling.

Erythema Nodosum in Children.—In discussing this rare disease Dr. Isaac A. Abt, of Chicago, said that the older and also the modern writers are not agreed upon the differentiation between the two varieties of erythema nodosum and erythema multiforme, but, he believes, that certainly erythema nodosum belongs among the exanthematous diseases, although Levene thinks that it is developed upon an angioneurotic basis and Fenger that it is due to a septic process. The disease occurs in anemic children or in those in a depressed condition from any cause, but it may occur in healthy individuals and generally appears from the second to the fourteenth year. Gastro-intestinal and other symptoms such as occur in exanthematous diseases are present at the beginning. The nodes which appear on the dorsum of the feet upon the legs, thighs or forearms are round or oval and vary from the size of a walnut to that of a hen's egg. They have no well defined border and two never coalesce. They are firm to pressure, and painful. The skin over them is tense, and at first bright red, but in a day or two this becomes dull read or bluish and subsequently undergoes the color changes observed in a bruise. Together with these changes there is observed a subsidence of the pain, swelling and constitutional symptoms; but there are usually repeated crops. The nodes may appear in the mouth and break down, forming ulcers. The duration of a crop of nodes is from eight to fourteen days, while the time from the appearance of the first symptoms to the disappearance of the last crop of nodes may be three or four and sometimes even eight weeks. Some writers on the subject have believed rheumatism an etiological factor in erythema nodosum, but that clinical observations have not upheld this theory. The pain present in erythema nodosum, upon which those who have held this idea have based their belief, is also present in other exanthematous diseases, notably scarlet fever, measles, and smallpox, and that therefore this belief may not be well founded. The pain during the prodromal stage was due largely to the tensity of the skin at the site of the nodes. Endocarditis, septic in form, and meningitis also occur at times. Some writers have claimed that there is a connection between tuberculosis and erythema nodosum, but this has been disproved, particularly by Kühn. However, the relation, as shown clinically, is an intensely interesting one. Infectious diseases do prepare the way for erythema nodosum and many sequelæ similar to those which occur after the exanthematous diseases are likely to follow.

Dr. Liebenthal, of Chicago, suggested that the confusion in the classification of erythema nodosum as distinguished from erythema exsudativum might be lessened by remembering that one begins on the dorsum of the foot while the other appears first on the dorsum of the hands, and that the microscopical pathological findings were very similar to those present in urticaria.

Whooping-cough—A Study of Seventeen Cases Treated with the Elastic Abdominal Belt.—Dr. T. W. Kilmer, of New York, said that he had applied this treatment to seventeen consecutive (not selected) cases and that the method was to apply a stockinette band extending from the axillæ to the hips and over this an elastic bandage of similar material to that used in elastic stockings, putting it slightly on the stretch and stitching the upper and lower edges to the stockinette band to prevent curling. If necessary to produce the desired results the bandage may be made tight. He showed charts of his cases indicating the ratio in frequency of the cough to the vomiting. During the first week of observation the child being only under placebo treatment this was as twelve to eight. After he applied the belt, at the end of one week he said the results were always marked, sometimes spectacular, and only in one case in eighteen did he fail to stop the vomiting, while in only six was there failure to stop or greatly lessen the cough, and in one case in which the coughing and vomiting had been entirely stopped by the application of the belt they began again when the belt was removed by the mother. He said incidentally that this method of treatment had been tried with success in the vomiting of pregnancy and in conclusion that he thought the application of the elastic belt should be given a fair and impartial trial in the treatment of whooping-cough, since

in his experience it had apparently aborted many cases and had practically stopped the vomiting in all but one of the other.

Dr. Bernhardt, of Butte, Mont., suggested that perhaps the impossibility of the inspiration might be the cause of lessened cough.

Dr. Kerley said that he had seen the cases reported upon and noted the particular efficiency of the treatment in children of one year in whom the administration of drugs is difficult.

Dr. Gilbert, of Louisville, Ky., suggested the danger of hernia, since this sometimes occurs in the new-born after the application of the ordinary abdominal binder, and asked Dr. Kilmer's theory as to the cause of favorable results.

Dr. Kilmer said, in closing, that the action of the belt was of course purely mechanical, that he had no case of hernia following the application of the belt and that in the cases reported he had given no other treatment and compared this treatment to the relief known to follow application of pressure over the stomach in sea sickness.

Malnutrition and Infantile Tuberculosis.—Dr. Louis Fischer, of New York, said that in the study of five thousand ordinary clinic cases of children belonging to the poorer classes the appearance of tuberculosis was noted in fifty-nine of them, and in seventeen hundred of the cases there was some form of pharyngeal or laryngeal disease, but no tuberculosis of the lungs or other organs. He said that of the tuberculous patients only two were breast fed, and in these the mothers were poorly nourished and in no condition to nurse their babies, and that most of the tuberculosis cases showed improper nourishment as shown by poor frame, weak bones, flabby muscles and other evidences of rickets. His cases had been corroborative of the facts shown in the literature on the subject, and he thought that the majority of tuberculosis babies were bottle-fed babies, therefore the importance of cow's milk. He said that opinion was divided as to the route of invasion in tuberculosis, but that there were good reasons for believing that either the bronchial or the mesenteric glands might be first infected, and mentioned Dr. Osler as favoring the former and Dr. Delafield the latter route to the lungs. As to prophylaxis, Dr. Fischer said that if possible all babies should be breast-fed, so that the danger of faulty feeding is lessened, and in this connection he said that perhaps the serum of mother's milk may contain an immunizing substance acting in the child antagonistically to the tubercle bacillus, and that fresh air and sunshine were of equal importance.

Dr. Jacobi, of New York, said that if he were asked what he would do with the tenement house baby if its mother were tuberculous he would say, don't allow her to nurse her baby, not that the milk was dangerous, although it might be, but because of the danger to the child because of her expectoration and the particles of sputum scattered about when she coughed. If the baby be removed from the mother its chances of growing up well and strong are greatly increased, but if it remains with the mother it will almost certainly become tuberculous. He said that milk from one cow is always dangerous, but that the danger is greatly lessened when a baby is fed with the mixed milk of a herd. He also said that intestinal tuberculariza tion is certain and that he had demonstrated tubercle bacilli in ascitic fluid post mortem in a case where there were no lesions of the mucous membrane of the intestines, thus proving that the bacilli may pass through healthy tissues and that this was true also of lung tissue. Infections through the nose also occur, but that in reality it is not an infection by inhalation for the bacilli lodge in the pharynx and larynx, and when conditions permit infection occurs from there through the lymph spaces to the glandular structures of the neck and mediastinum.

Dr. W. B. Ulrich, of Chester, Pa., said that there is a tuberculous diathesis in children of tuberculous parents and that the beginning of prophylaxis should be in the control of marriage and that a tuberculous mother should not have children.

Dr. Fischer said, in closing, that the tuberculous mother certainly should be isolated from her child, and also, if possible, from her husband. He said also that a large percentage of children infected with tubercle bacilli had been previously fed upon condensed milk and that this was the cause of a poorly nourished condition of children.

BOOK REVIEWS.

Lessons on the Eye for the Use of Undergraduate Students. By Frank L. Henderson, Ophthalmic Surgeon to the St. Mary's Infirmary and the Christian Orphan's Home, Consulting Oculist to the St. Louis City Hospital, The Wabash Railroad, etc. Third edition. P. Blakiston's Son & Co., Philadelphia.

This book will no doubt serve an excellent purpose among the very numerous examples of its class, intended simply for students. It is a little hard to distinguish individual merits where much is necessarily omitted, and the chief virtue seems to be the selection of what is indispensable for passing examinations. In this book, however, the virtue of brevity is not sacrificed, and a broader point of view is to a certain extent retained. The illustrations are better than those in other books of the same caliber and not too numerous.

New Psychology. By J. P. Gordy, Ph.D., LL.D., Head of the Pedagogical Department of the Ohio State University. Hinds and Noble, New York.

Psychology has become of ever-increasing interest in recent years for the physician. The newer psychology especially, because of its practical bearings, has proved useful. The present little manual serves well the purpose of an introduction to the new psychology and while it is meant for the teacher rather than for the physician it cannot but be suggestive to those interested in varying mental states. Some idea of its popularity may be gathered from the fact that though the first edition was published in 1898, it had reached its twelfth edition before 1903, and is still in demand. The book was written principally for the benefit of that large number of progressive young teachers who have not enjoyed the benefits of a college education and consequently is likely to be of service especially to those who have not had previous instruction in psychology. The arrangement of the book is such as to commend itself and there is a logical gradation in the method of imparting successive steps in psychology that constantly keeps up the interest.

ORIGINAL ARTICLES.

MANAGEMENT OF FEVER IN CHILDHOOD.[1]

BY EUGENE W. MURRAY, M.D.,

OF NEWARK, N. J.;

ASSISTANT PHYSICIAN, BABIES' HOSPITAL; ASSISTANT PHYSICIAN, NEWARK CITY HOSPITAL; ASSISTANT SURGEON, NOSE AND THROAT DEPARTMENT, ST. MICHAEL HOSPITAL.

By fever we understand an abnormal elevation of the body temperature continued throughout the day, or if not continuous, at least intermittently repeated, due to some infection, some local inflammatory process, or to some unexplained disturbed state of the nervous system, and presenting the phenomena of rise of temperature, quickened circulation, marked tissue change and disordered secretions.

No symptom of disease was more carefully studied by the ancients than the temperature as estimated by the rate of the pulse, and Hippocrates based his prognosis upon the height of the temperature. From the time of Galen and Aristotle down to long after the discovery of the circulation of the blood by Harvey, the heart was believed to be the source of this heat, and it was variously thought to be due to an overproduction, to obstruction to the flow of the vital spirit, to evil spirits, and to various circulating humors.

The chemical era, however, finally recognized that the heat was due to oxidation, and hence the production of heat was not limited to any one organ, but was generated in all parts of the body.

Sanctorius, of Padua, and Galileo, toward the close of the sixteenth century, invented thermometers. These were first made of alcohol, but Halley in 1680 recommended the use of mercury in thermometers, and Fahrenheit first presented his in 1720, and Celsius his centigrade in 1742. Boerhaave, in the early part of the eighteenth century, was probably the first to use the thermometer in fever, and his practice was ably elaborated by his pupil Dr. Hann, but the thermometer did not come into general clinical use until Gavarret, in 1839, and twenty years later, Zimmermann, Traube and Wunderlich urged its advantages.

Since this time we have swung from an overestimate of the prognostic value of the height of the temperature to the recent belief that its greatest importance lies in its diagnostic advantages, and as a day-to-day indicator of the progress of the disease.

Before we can well understand the management of fever we must comprehend the pathology, and before we can well understand the pathology we must comprehend the normal mechanism of animal heat. The sole cause of this heat is a chemical process, a combustion of food substances by the oxygen taken in by the animal.

About four-fifths of the total body-heat is produced in the skeletal muscles, through an oxidation whereby oxygen is absorbed and carbonic acid given off, though the processes passed through are probably much more complex than mere oxidations. The other one-fifth of the animal heat is furnished by the secreting glands and alimentary canal during digestion; hence the additional ability to withstand cold after a hearty meal. Even the thermometer in the mouth will show a higher reading just after a meal than before. During acute fevers, glandular activity and digestion are at a low ebb, and almost the entire heat-production in these conditions is probably due to oxidation or changes in the muscular system,—hence the wasting.

Any muscular or mental activity, or the taking of food, will slightly raise the temperature, though external surroundings do not much affect the temperature of adults. But the babe because its equilibrium regulating apparatus is undeveloped, and the convalescing adult because his is impaired, are easily made colder or warmer by sudden changes of the external air and by internal disturbances.

A word as to the physiology of heat-regulation: The equilibrium of the body temperature must be governed by the relation of the heat-loss to the heat-production, and as the one increases so must the other, and all of this mechanism must be under the control of some finely adjusted nerve-governor. Various theories have been offered, ranging from McAllister's three centers, *viz.*, a thermogenic, or heat-producing center; a thermolytic, or heat-dispersing center, and a thermotoxic, or heat-controlling center, to Schaffer and Moore's belief that the vasomotor mechanism in the medulla oblongata is sufficient to arrange all regulation of heat-loss to heat-production. There is no known structural difference before or after the heat-regulating power has developed, but this power appears to be associated with the control over the skeletal muscles and blood vessels.

Now as to the pathology of fever: Its cause must be an overproduction of heat or a diminished loss of heat, or both. This may be due to anything that interferes with the vasomotor regulating apparatus, or to anything that increases chemical activity, be it grandular, muscular, or metabolic.

Probably most fevers are due to poisoning from some source, the character of the fever of course depending upon the kind of poison. Anything that irritates or excites the brain may interfere with heat-regulation and cause fever to occur. This is especially noticeable in convalescents and

[1] Read before the Practitioners' Club, December, 1903.

infants, as too much excitement, overeating, etc., causes a return of fever in the convalescent, or a febricula with the cause unfound in the infant, and all meaning a vasomotor ataxia, or a thermotoxic power impaired or undeveloped.

A malarial paroxysm is perhaps the best type of the immediate stoppage of heat-loss, with a consequent sudden enormous rise of temperature. As the infected red blood corpuscles burst from the presence of the matured plasmodia, the first impression on the nervous system is to cause a sudden irritation of the vasomotor centers, and a resultant contraction of the peripheral vessels, and the symptom is a chill more or less pronounced. The internal temperature, perhaps partly from the poison, certainly largely from the obstructed heat-loss, rises rapidly and often to a great height, which is sustained until the now superheated skin and overstimulated sweat glands begin to pour out a profuse perspiration and the heat-loss first exceeds and then equals heat-production and the normal equilibrium is once more established.

Brasch has examined the spinal cord of a number of persons suffering from fever, and found that the outline of the ganglion cells were rounded, that they appeared swollen, and were much paler than normal. The swelling extended to the protoplasmic processes. These results are thought to contradict those of Juliusberger and Meyer, who found only a collection of fine granules in the center of the cell. On the other hand, the changes correspond closely with those described by Goldscheider and Flatau as a result of experimental febrile conditions. These changes disappear very rapidly if the fever subsides, as appears to have been the case in one spinal cord from a patient suffering from pneumonia. In hectic fever these changes do not occur.

It is possible that if fever persists for a sufficient length of time retrograde changes may take place.

Under the head of general treatment sleep is a very important point, and must not be disturbed, except in conditions of sepsis and depressed brain action. In both these there is no sound sleep, but sopor, which should be interrupted. In sepsis (as diphtheria and others) this rousing from sopor is an absolute necessity. Unless they are aroused frequently, to be fed sufficiently, and stimulated freely, the patients are apt to die. Besides, in most of the cases, the temperature is not high, and there is no contra-indication to feeding on that account.

If, on the other hand, the fever is a continued one, or even continuous for a few days, we must then analyze the conditions. Is the amount of fever due to the germ, to the local inflammatory conditions, or to the disease *per se?* If it be any one of these, our first duty is to keep the patient cool and quiet. And how important quiet is when we consider that every excitement causes restlessness, and this means muscle movement through which heat-production is increased.

It will frequently be necessary to give hypnotics, not only for the brain-rest, but for the good to be obtained from absolute muscle-rest. The bowels should be kept carefully cleaned out, not alone for the relief of the liver, and therefore of the blood, but also to prevent fermentation, decomposition and reabsorption of all the products of bowel infection.

Before we consider the medicinal management of fever—that is, of lowering the temperature—we should analyze its causes, carefully note the immediate effects on the individual, whether dangerous to the organism or not, consider the probable future of the fever, and also question if this is not nature's method of combating the toxicity of the germ or germ products. In the first place a high temperature, that is, 104° F. or more, whether in a test-tube or artificially produced in infected animals, is not conducive to the activity of many germs, notably the pneumococcus or the bacillus of Eberth.

Whether in the human animal a temperature of 104° to 105° F. kills off the above germs rapidly, or better forms antitoxin to combat them, would be hard to decide, and certainly it would be hard to convince us that a temperature of 104° F. or above was desirable in pneumonia or typhoid fever. The first question to ask in considering treatment of a case is, Is this temperature high enough to antagonize with remedial agents or not? If high, is it dangerous to life either immediately or remotely? We all know that the system can sustain for a short time a temperature of 105°, or even 106° F., without danger or damage, while a long-continued temperature of 101° F. is serious to the heart, muscles and nervous system.

With a short-lived fever, as that of a malarial paroxysm, or influenza, if it is high it may cause some symptoms that are very unpleasant, and which may call for treatment, but the fever, as such, requires no treatment. If we now decide that this fever is in excess of that due to the disease *per se,* we must seek the additional cause, and with each disease we know where to seek its local manifestations.

In the varied local inflammations it would seem to indicate pus, as in appendicitis, pleuritis, synovitis, otitis media, etc.

The medicinal management of fever must be governed by each individual case. Strychnine, caffeine, cocaine and atropine all raise the temperature by increasing muscular and cerebral activity, and the latter by reducing heat-loss by preventing perspiration. Alcohol, nicotine and morphine diminish temperature; the first two by relaxing the blood vessels and increasing perspiration, and the last by preventing all glandular and molecular activity.

Clinically, then, with high fever we should stimulate with alcohol, but with depression we should stimulate with strychnine. Antipyrin is the most efficient agent in depressing the temperature, but the profuse perspiration that it causes is often very prostrating. Acetanilid does not cause as profuse sweating, but is more directly

depressant to the heart, hence it is well to combine with it a little caffeine or other heart tonic.

Phenacetin is the safest of these three so far as depression is concerned. If the temperature still keeps too high, we can in short fevers use the coal tar products in proper doses a few times, perhaps, carefully noting the effects on the heart, but generally the use of cold in some form is more satisfactory.

This leads me to speak of the hydrotherapeutic management. A carefully regulated ingestion of ice or cold water also tends to diminish the temperature. In young children and infants, where they are not much prostrated, the rectal irrigation with the patient in the Sims' position gives good and immediate results. In cases where there is great prostration the ice cap to the head or the sheet pack may be employed. Given as follows it produces the minimum amount of shock. After the removal of all clothing take a sheet dipped in warm water, and wrap carefully and smoothly about the child; over this a second sheet wrung out of cold water is to be applied. After the application of the second sheet gentle friction with the hands to prevent capillary engagement is indicated.

When the outer sheet becomes slightly warm, cold water can be rubbed over by means of a sponge. In the application of this treatment two symptoms should be constantly kept in mind. One is the character of the breathing, and the other is the tendency to cyanosis. Should the breathing become irregular, or the lips blue, during the application of this treatment the child is to be removed from the pack and placed between warm blankets. The application of this treatment will require from ten to fifteen minutes. At the end of this time the child is to be rubbed until the skin is dry and has a good healthy glow. The repetition of this treatment will depend upon the recurrence of fever, and its influence upon the patient. In cases where the fever has been complicated by convulsions, it is always best, after the child has been placed in bed, to apply cold cloths to the head or use a water bag for a pillow.

If the temperature, even though brief in duration, is so high as to be dangerous to life, as occurs in insolation, in which such a chemical or nervous change has taken place from the external heat, so that heat-loss seems to be impossible, nothing is so effectual or is so likely to save life as immersion in a tub of cold water gradually made colder by ice.

Fever consumes nitrogen, oxygen, carbon, water, and also salts. These losses must be repaired with great care. For fever at the same time diminishes the secretion of saliva, and of gastric juice, probably also of the pancreatic secretion. Besides, it renders the stomach hyperesthetic, consequently nausea and vomiting ensue; it also impairs the absorbing power of all the mucous membranes. Therefore we have a lowered capacity for all kinds of food.

Toxic Fevers.—In no class of cases that a physician is called upon to treat are the results more satisfactory than in those due to products of fermentation, when the intelligent cooperation of the parents or of a trained nurse can be secured. If the parents themselves are lax in discipline, and are unable to govern the child, an efficient trained nurse must be secured, into whose hands the exclusive management of the child should be placed. The essential part of the treatment is that relating to diet. It has been my practice to clear the digestive tract of all fermentative products. Then keeping the fever under control by cold sponging, ice cap or rectal irrigation, I proceed to combat the toxemia by stimulating the organs of elimination, viz., the kidneys, bowels and skin.

I do not believe that in all cases all food must be stopped, but, on the contrary, I do believe that the patient should be sustained by proper food. A small amount of peptone is absorbed both in the stomach and rectum. In moderate fevers some sugar is absorbed, also albumin, and fat in but small quantities, because of its tendency to become acid; starch finds its saliva more or less diminished,—thus its amount must be carefully estimated. Giving in undue quantity may result injuriously by acting as a mechanical irritant, and give rise to fermentation. In ordinary fevers the food must be liquid and rather cool; in vomiting, cold; in respiratory diseases, warm; in collapse, hot. The best feeding time is the remission. In intermittent fevers nothing should be given during the attack except water, or acidulated water, with now and then an alcoholic stimulant. In septic fevers, nothing should be given during a chill except cold or hot water, according to the wishes of the patient, with an alcoholic stimulant. The scheme suggested by Dr. Coit, of this city, for feeding children from twelve months to two years of age who are suffering with fever, seems to me to be a very accurate and simple way in which to manage the diet in these conditions, viz., when the evening rectal temperature is 100° F. or above it, no food except milk containing fat two per cent., proteid one per cent., sugar five per cent., should be employed, or better still, cut down the regular milk formula which the child is taking according to this plan, which should be advanced in a progressive series:

	ozs.	ozs.	ozs.	ozs.
First, boiled regular milk.....	Three	ounces, then 4,	then 5,	then 6, then 6½.
Boiled water...	Two	ounces, then 2,	then 1,	then 1, then 1.
Lime water....	One-half	ounce, then ½,	then ½,	then ½, then 0.

When the evening rectal temperature is below 100° F. advance one step in the above plan each day until full strength milk is again used. When the evening rectal temperature is steadily below 100° F., yet above normal, allow only besides the milk, bread and butter with first, third and fifth meals, and broth and dextrine biscuit with midday meal.

When the evening rectal temperature is steadily normal allow cereals and sterile cream with first and fifth meals, and when this is well borne add

to the midday meal gradually, first starchy vegetables, milk puddings, green vegetables, then eggs, white meats and finally red meats.

I wish to call your attention to the following as one form of fever which defies both medicinal and hydrotherapeutic measures of treatment:

Inanition or starvation fever is a condition depending upon insufficient feeding or lack of assimilation. It is common in early infancy, and would undoubtedly be much more frequently recognized were the temperatures of infants taken more often. It usually develops under one of the following conditions: First, when a child refuses all food, whether from the breast or bottle, or can be made to take only so small an amount that it is not enough to support life. Second, when the food given is entirely inadequate, as when a child is nursing upon a dry breast, or one in which the milk supply is so scanty that it gets practically nothing. Third, when the character of the food is improper. Fourth, when the infant at birth has such feeble powers of digestion, because it is premature or delicate, that it is unable to digest and assimilate enough of the food given to sustain life. Fifth, when a sudden change of food is made to one so difficult of digestion that the child is unable to assimilate it. This may happen after sudden weaning.

The temperature is variable; in the newborn it is often high, but may be subnormal. The pulse is always weak andrapid. The existence of inanition in young infants presupposes only the feeblest powers of digestion and assimilation. If possible a good wet nurse should be secured. This is one of the few conditions in which wet nursing is almost indispensable. If one cannot be obtained, milk containing 1 per cent of fat, ½ per cent. of proteid and 5 per cent. of sugar, thoroughly alkalized and peptonized, should be given. If food is not readily taken it should be given by gavage. This is frequently necessary, as very many of these infants will not take food at all, or only in such small quantity as to be insufficient for nourishment. If there is vomiting this percentage may need to be lowered. As soon as the child begins to improve, one must be careful about increasing the food too rapidly, for renewed vomiting with aggravation of all the other symptoms is sure to follow such a mistake. The temperature should be controlled by cold sponging, cold to the head and heat to the extremities. As soon as the child begins to take food and assimilate it the temperature will disappear.

The first thing to do in case of inanition is to examine the mother's breasts and milk, which usually discloses one of the following conditions: First, overrich milk and quantity abundant. Second, milk poor in quality and scanty with breasts flabby. Third, quality good, amount scanty. Fourth quantity abundant, quality poor.

Proper management of the mother by stimulating her milk making capacity sometimes avoids the unpleasant necessity of a wet nurse, or artificial feeding.

The foregoing example illustrates a form of fever which can be successfully treated only by dietetic measures, and plainly indicates our duty in determining the cause, whether it be toxic, or inflammatory, or some disturbed nerve state.

TWO CASES OF PARALYSIS OF THE ULNAR NERVE; ONE FOLLOWING A SEVERE ATTACK OF TYPHOID FEVER; THE OTHER CAUSED BY PRESSURE DURING OCCUPATION.[1]

BY JAMES HENDRIE LLOYD, A.M., M.D.,
OF PHILADELPHIA.

Isolated paralysis of the ulnar nerve from any cause is, I should judge, not a frequent affair, in spite of what some authors say to the contrary. Personally I have seen but few cases of it in a somewhat extended neurological experience. In view, therefore, of the fact that the isolated paralysis of any nerve gives unusually favorable opportunities for the study of its relations and actions when in health, and that these relations and actions of the ulnar nerve are particularly striking, it is always worth while to study these individual cases with more than ordinary care.

The causes of paralysis of the ulnar nerve are very numerous, but the great majority of them belong to the category of wounds and injuries. I saw an instance some years ago in which this nerve, along with the ulnar artery, was completely severed by broken glass in the case of a house-painter who fell through a sky-light. As I have said elsewhere,[2] all sorts of cuts from all sorts of weapons may injure the ulnar nerve, because this nerve in some parts of its course, especially near the elbow-joint, is unusually exposed. Gunshot and pistol shot wounds have involved the ulnar nerve. Ballet recorded an instance in which the nerve was injured by prolonged pressure in a glass-blower while at his work. Briddon related a case of sarcoma of the ulnar nerve, which eventually led to amputation at the shoulder-joint and exsection of the scapula. S. Jones saw a case of neuroma of the ulnar, causing paralysis of the nerve. F. J. Lutz reported a case of habitual dislocation of this nerve, and Blattmann wrote on this subject as early as 1851. Dr. H. R. Wharton, of Philadelphia, has also reported a case of dislocation of the ulnar nerve, and has collected 13 cases from the literature.

This accident may be caused by fracture of the humerus or by dislocation of the elbow, or by direct violence, such as muscular effort or violent flexion of the forearm. Fracture of the bones of the upper extremity has more than once caused paralysis of the ulnar. Panas narrated a curious case of such paralysis that did not occur until twelve years after a fracture at the elbow, and was possibly due to a thickening of the nerve sheath caused by irritation from redundant callus. Avezon related a case caused by fracture

[1] Read before the Philadelphia Neurological Society at its regular meeting, December, 1903.

[2] See the author's article on "Diseases of the Cerebrospinal and Sympathetic Nerves" in the Twentieth Century Practice, Vol. XI, from which most of the above references are taken.

of the humerus. Pressure palsy of the ulnar nerve caused during sleep is evidently not nearly so common as this palsy in the musculospiral nerve, and yet it has occurred. Brauns (quoted by Gowers) advanced the theory that when the nerve is compressed during sleep, the pressure is more likely to occur at the shoulder than near the elbow and especially when the arms are held in the position in which the hands are clasped behind the head.

This subject of pressure is of particular significance in all cases that occur when the patient is unconscious, whether this unconsciousness comes from sleep, from drunkenness, from ether anesthesia, or from the poison of typhoid fever. Thus, within the past month I have seen paralysis of both ulnar nerves in the case of a large, stout woman who had been under ether for a long time for a pelvic operation. The palsy, however, was slight and transient, but the complication was doubtless due to pressure, probably with the arms resting on the edge of the table. Gowers refers to a case in a woman due to pressure during a hard and protracted labor.

Isolated paralysis of the ulnar nerve due to a blood infection presents a very different problem. It is not, in fact, easy to understand how a general systemic poison should cause such an isolated paralysis. It is too well known, of course, to need more than mere mention, that a general multiple neuritis is not uncommon from a systemic poison. Thus alcoholism, diphtheria, and typhoid fever may cause a polyneuritis, but except in the case of lead, which often selects the interosseous and some other branches of the musculospiral nerve, the selective action of any systemic poison for one isolated nerve is certainly extremely rare. The selective action of wood alcohol for the ganglion cells of the retina furnishes another example. In the case of typhoid fever some effort has been made to show that this poison has a selective action in some cases for the peroneal and ulnar nerves, and Sir James Paget is usually quoted as authority. But Sir James Paget's original communication on this subject[1] is a mere paragraph and very unsatisfactory from a neurological standpoint. Moreover, he does not mention the ulnar nerve, but only the peroneal or anterior tibial.

Measles has been reported as the cause of a peroneal type of muscular atrophy, in which the lesion is possibly a peripheral neuritis. Tooth[2] described such an affection and suggested measles as a cause, and Omerod[3] reported three cases in one family following measles. But in his case a family predisposition existed, and the cases are not entirely conclusive. I formerly reported a case of widely extended multiple neuritis following typhoid fever,[4] in which case I have since questioned whether excessive alcoholic stimulation and the cold baths may not have been largely responsible. But these cases of polyneuritis leave unexplained how in a very few cases of typhoid fever the ulnar nerve alone is involved.

That isolated paralysis of the ulnar nerve following typhoid fever is a comparatively rare affection, seems to be proved by Liepelt, who has recently gone over the whole literature and been able to find only 16 cases, to which he added a seventeenth. Liepelt studied the reports of 12 of these cases specially, and found that in 9 cases the paralysis began during convalescence from the fever. Pain was an early symptom in 8 cases, and the electrical irritability was diminished in 11 cases. Atrophy was present in 9, and sensation was involved in most of them. In 3 cases the patients recovered and 3 improved.[5]

The case which I desire to report is as follows:

H. F. L.; white, male; aged 29 years, was admitted into the Methodist Hospital as a private patient of Dr. T. L. Coley's in May last. The diagnosis was clearly typhoid fever, and the case pursued a very severe course. Not to go into minute details, which are not essential here, it is enough to say that hyperpyrexia with extreme prostration was a marked feature of the case, and that the patient suffered several alarming hemorrhages from the bowels. The duration of the attack, as shown by the dates of admission to and discharge from the hospital, was about nine weeks, which included a relapse. When the patient was at his worst I saw him in consultation at Dr. Coley's request. At that time the case presented a very grave aspect; the patient was profoundly unconscious, with extreme jactitation of the muscles (subsultus tendinum) and a pulse ranging as high as 144. About that time the hyperpyrexia was at its highest. On one occasion the temperature rose to $106^{2}/_{5}^{\circ}$ F., and for a period of about fourteen hours it was continuously above 105° F. During this crisis the patient was kept up with full doses of whisky, and during the course of the fever he was either sponged or plunged *secundum artem*.

After his discharge from the hospital convalescent nothing was reported amiss by him until some weeks later, when he turned up again with distinct paralysis of his right ulnar nerve. Dr. Coley is quite sure that the patient did not complain of this affection before he was discharged. He himself says that he first noticed the symptoms before he left the hospital, and that these first symptoms were weakness and wasting, but that he had little if any pain either at that time or later. His condition on Dec. 22, 1903, was as follows:

Motor.—There is marked weakening of the grip, and a tendency on flexion at the wrist for the hand to bend toward the radial side. There is partial loss of adduction of the thumb, shown by inability to touch the base of the little finger with the tip of the thumb. There is inability to separate the fingers, with almost total paralysis of the little finger. There is also an approximation to that condition called by the French the *main en griffe*, but this curiously is seen only in the little finger. All these paralyses are exactly such as we should expect from paralysis of the ulnar nerve. That nerve supplies first the ulnar flexor of the wrist—hence the deviation in flexing

the wrist. Next it supplies the inner part of the deep flexor of the fingers—hence an enfeeblement of the grip. It also supplies the interosseous and two inner lumbrical muscles, the actions of which are essential in the finer movements of the small joints, and which muscles flex the first phalanges and extend the second and third phalanges. Hence the tendency to *main en griffe*, which consists in over-extension of the first

Fig. 1.

Paralysis of the ulnar nerve following typhoid fever.

phalanges and flexion of the last two small bones. It also supplies the adductor of the thumb, hence the restriction of motion in that member; and finally it supplies the three small muscles that give flexibility to the little finger, hence the limitation in range of that member. As the two outer lumbrical muscles are not supplied by the ulnar, but by the median nerve, the tendency to *main en griffe* is more marked on the ulnar side of the hand, as is the case very markedly in this patient; in fact, the little finger alone has assumed that position.

The Electrical Reactions.—To faradism the irritability is practically abolished in all the affected muscles. By picking out the motor points and comparing with the sound side it is possible in this case to demonstrate beautifully that the flexor profundus digitorum is partly impaired and the flexor carpi ulnaris entirely so. The essential muscles of the hand are much involved; neither the interossei nor lumbricales contract to the current. This is also true of the adductor of the thumb and of the three muscles (flexor, abductor and opponens of the little finger) none of which responds to faradism. The current, in fact, reveals clearly the extent of the damage.

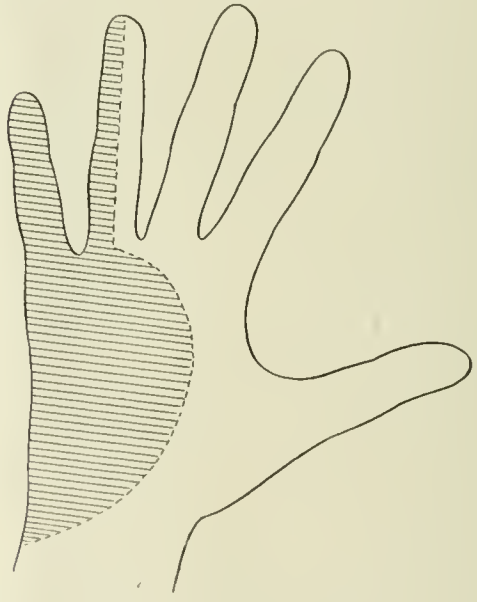
Atrophy.—All the paralysed muscles are much wasted, giving the hand a very characteristic appearance, due especially to the wasting in the interosseous spaces and in the thenar and hypothenar eminences. The flexor carpi ulnaris is also flattened.

Sensation.—There is very marked anesthesia, and this follows the classical lines, as in the diagram. It is complete, however, both to faradism and to touch only on the fingers—the whole of the little finger and the inner half of the ring finger. On the palm there is no tactile anesthesia—answers are correctly made, but to faradism there is still diminution. Thus faradic and tactile anesthesias are not coextensive. It is rather curious that the patient asserts that there is some numbness on the *back* of the hand to the faradic current, but this is probably because the current is so readily transmitted through the whole thickness of the hand that he confuses the anesthesia due to the ulnar and locates it on the dorsum. Tactile sensation is perfect on the back of the hand.

The query arises in such a case as this: Is the lesion due to a blood poison, *i.e.*, the poison of typhoid fever, or is this, and other cases like it, merely a pressure palsy of the ulnar nerve occurring during the delirium and unconsciousness of profound typhoid intoxication?

I believe that the latter theory is the correct one. When we consider the chances that the arm

Fig. 2.



Anesthesia in a case of paralysis of the ulnar nerve following typhoid fever.

of an unconscious patient may be thus injured by pressure, or by the necessary manipulations in giving him the plunge baths, we must at least acknowledge the probability of such an origin—and this theory is in accord with the fact that all isolated paralyses of the ulnar nerve are, as I have shown, clearly due to trauma or some local lesion.

The second case is one of pressure palsy of the ulnar nerve, and is not unlike the case, already re-

ferred to, which was observed by Ballet, in a glass-worker. It illustrates several points, among them the insidious onset and gradual course, so that the patient did not recognize its true cause; and, second, the absence of involvement of the sensory neurons. This latter observation is in accord with a well known law in neuropathology.

B. M.; 20; white, male; clerk. For a year and a half the patient has been employed as a

Fig. 3.

Paralysis of the ulnar nerve caused by occupation.

clerk in the Pennsylvania Railroad. During all that time he has been writing steadily, and has acquired the habit of leaning on his left forearm, which he places on the sharp edge of the desk. The arm is held in such a position that the edge of the desk is pressed hard and deeply into the ulnar side of the forearm just below the elbow-joint. The point of greatest pressure is about one and a half inches below the inner condyle of the humerus, and just where it is possible to make direct pressure on the nerve after it has passed beneath this condyle and before it becomes covered by the muscular masses of the forearm.

The first symptoms noticed by the patient were slight tingling in the region of the crazy bone, and the beginning wasting of the intrinsic muscles of the hand. He has never had pain in the nerve, nor is there the slightest degree of anesthesia. This latter point has been most carefully tested.

The condition at present is as follows: The wasting is very marked in the interosseous spaces, and in the thenar and hypothenar regions. The power of adduction in the thumb is still preserved to some extent, but the power of the three small muscles of the little finger is lost as is also the power of separating the fingers. Flexion at the wrist is well preserved. There is a slight tendency to the position of the *main en griffe* in the little and ring fingers, but no fibrillation.

The points of chief interest in this case, as already pointed out, are the fact that the pressure has been long continued, and that therefore the symptoms have been of very gradual onset, and are not yet complete. The absence of anesthesia, with the presence of marked wasting, shows how in cases in which the cause acts gradually the sensory filaments may entirely escape.

APPARATUS FOR NITROUS OXIDE-ETHER ANESTHESIA.

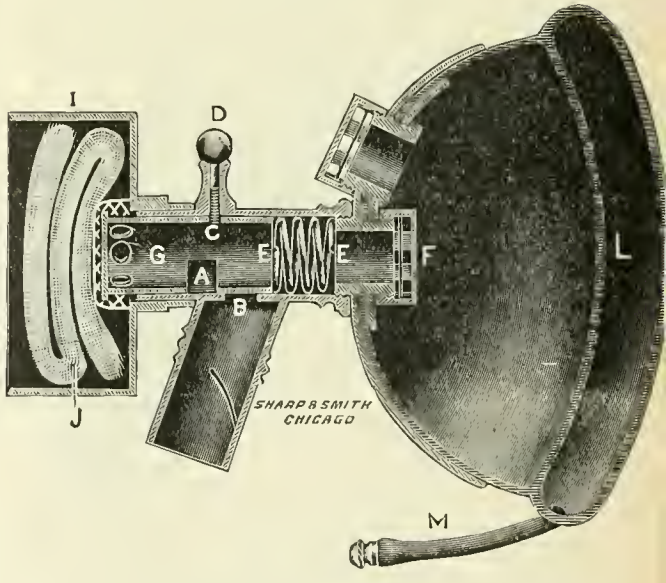
BY WELLER VAN HOOK, M.D.,
OF CHICAGO.

THE advantages gained by preceding ether anesthesia with nitrous oxide are numerous and striking. The patient goes to sleep in from one to three minutes, the beginning of the anesthesia is not unpleasant to the patient, and the total amount of ether required for anesthesia is much diminished. The writer was first impressed by the value of this method when he saw it used in the London hospitals, in 1895.

For some time the writer has used this method in his clinical work as well as in private practice, largely with the skilled assistance of Dr. D. H. Galloway. And the desire to obtain a very simple apparatus has induced him to devise an attachment for an ordinary nitrous oxide face-piece, so that the vapor can be substituted for nitrous-oxide gas at will.

Fig. 1 represents the face-piece in common use, invented by W. W. Harrington, of Carrollton,

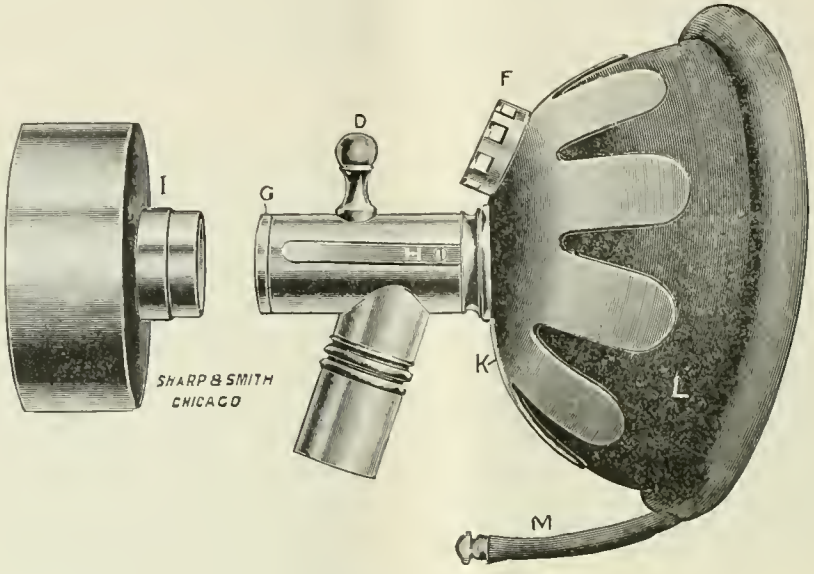
Fig. 1.



Ohio. The slide *G* when drawn out allows the patient to breathe air through the apparatus, but when pressed home and held by the spring *H*, the patient breathes nitrous oxide from the bag. The expired air and gas are forced out through the valve *F*. An assistant stands ready to turn on

more gas from the tank so that the bag may be kept as nearly full as desired.. When the patient is asleep, which requires about sixty seconds, the cap *I* is slipped over the valve *G*. Ether vapor is

Fig. 2.



then inhaled by the patient, the gauze *J* having been previously saturated.

In practical use, all preparations having been made, the bag filled, and the assistant being ready to turn on more gas as needed, the patient is allowed to breathe air a few times through the

any time until the patient has been under the influence of ether for several minutes.

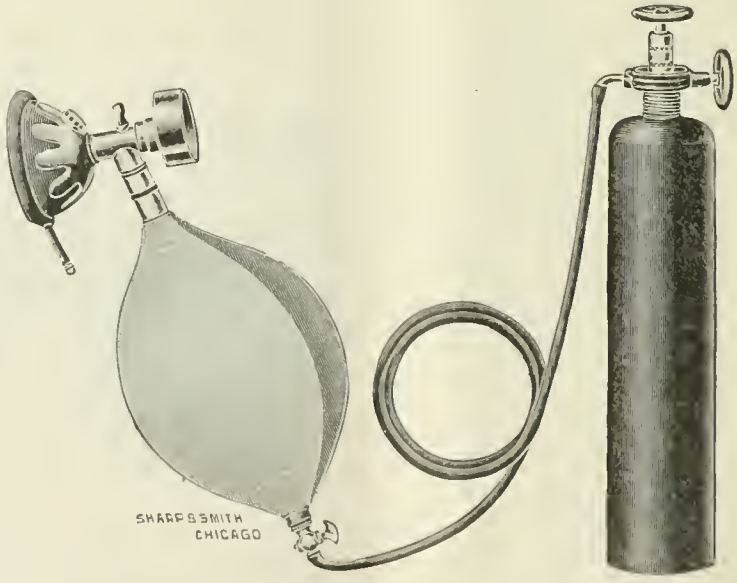
An extensive experience with this apparatus has given me confidence in its simplicity and use-

fulness. By using the 25-gallon tanks of liquid nitrous oxide the anesthetizer can transport the apparatus without prohibitory discomfort.

The following is a technical description of the apparatus:

Fig. 1 shows the external view and internal con-

Fig. 3.



valve *G*. When the gas is turned on the patient is informed of the fact. After he has breathed a few times through the ether cap, and respiratory reflexes are abolished, the ordinary ether cone may be substituted for the apparatus. It is most important that air should not be admitted at

struction. An opening, *B*, underneath the body of the inhaler, admits the nitrous oxide gas through a similar opening. *A*, in the sliding tube *G*, fitting inside of and projecting beyond the rear portion of the main body. The projecting portion is perforated for the admission of ether by the slipping

on of the container *I* which liberates the sliding tube *G* by lifting the spring catch *H*, at the same time closing the inlet *B* and shutting off the flow of gas. The sliding tube is prevented from rotating by the screw-pin *D*, which works in slot *C*. The inhaling and exhaling valves—the former internal, the latter external—consist of two thin disks of mica, *FF*, which are enclosed in open circular cages. The inhaling valve is opened in respiration by being drawn against the front of the cage, the exhaling valve being closed by the pressure of the outside air. In expiration both disks are thrown against the further ends of the cages, opening the exhaling and closing the inhaling.

The soft rubber face-piece consists of a hood, *L*, with an inflatable edge cushion attached to a metal frame, *K*, which is screwed on to the inhaler. The frame which preserves the shape of the hood may be readily detached for cleansing by unscrewing the nut which holds it to the neck of the inhaler. The cushion is inflated through the nipple *M*. The best adaptation to the face is obtained when it is partially distended.

The pure gum gas-bag with stop-cock, connecting hose and steel cylinder (Fig. 3), completes the apparatus.

A BRIEF REPORT OF FOUR YEARS OF GENITO-URINARY WORK IN THE SECOND SURGICAL DIVISION OF MOUNT SINAI HOSPITAL.*

BY HOWARD LILIENTHAL, M.D.,
OF NEW YORK.

ON the first of December, 1899, the surgical side of Mt. Sinai Hospital was divided into two separate, equal continuous services. The following is a report of what is known as the Second Surgical Division, of which the writer is the attending surgeon and Dr. Joseph Wiener, Jr., and Dr. Charles A. Elsberg, adjunct attending surgeons. This report must of necessity be extremely brief because although the genito-urinary portion of the work has been only about eight per cent. of the total surgical work of the division, yet the number of cases is so great that in spite of their extremely interesting character there is room for only the most superficial discussion. It is our custom, however, to publish in the volume known as Mt. Sinai Hospital Reports every case resulting in death or failure, while only the most interesting or atypical cases among the successful ones are printed in detail. All histories in the present paper are from the year just finished and ending December 1, 1903, those of the other years having been published as stated.

The service is a continuous one, the attending surgeon and both of the adjunct surgeons being on duty the entire year, with the exception of vacation when one man at a time may be absent. A daily visit to each patient is made by the attending surgeon and one adjunct surgeon whose work it also is to attend certain cases of emergency when it is not possible for his superior to be present. The other adjunct surgeon is present on regular operating days to assist or operate as the attending surgeon may require. The adjuncts alternate in their duties every three months.

The total number of genito-urinary operations in the four years was 186 of which 23 were followed sooner or later by death before discharge from the hospital; an apparent mortality of 12.3 per cent. or about 2.3 per cent. higher than the total mortality of the division. In considering this mortality rate it is but fair to say that it has been very decidedly influenced by the fact that patients are rarely discharged from the hospital before the termination of the case. If an operation for malignant disease has been undertaken, for example, unless the wound heals and a local cure has been accomplished the patient is usually permitted to remain until the end, often a matter of weeks or months after the operative recovery.

*Read before the Genito-Urinary Section of the New York Academy of Medicine on January 20, 1904.

During the year ending December, 1903, there were 51 operations with seven deaths.

At first sight these figures would seem to indicate that an incision into the kidney must be more dangerous than the total removal of the organ. This has not been our experience, however, considering the different conditions for which operation was undertaken. Thus, two deaths following nephrotomy for impacted ureteral calculi were evidently due to anuria present before operation and not relieved by it. Deaths following nephrotomy for acute and chronic nephritis, septic nephritis and hemorrhagic nephritis are also to be expected in the majority of cases.

The oblique incision parallel with the ribs is the one usually employed by us. After a simple nephrotomy the wound in the kidney is partially closed with catgut sutures, a drainage tube being carried down to the pelvis through the parenchyma between the sutures.

A table devised by the writer has been found very serviceable in operations about the kidney, a smooth slightly convex metal rest being so placed that when the patient lies upon his side he can be raised by means of a crank into the proper position. When the operation has been completed, but before the wound is closed, the patient may be slowly let down while the incision is held open with retractors thus fully exposing the depths. Hemorrhage which may appear on release of tension as the body assumes its normal position will be seen at once and can be controlled with ease.

Cystoscopy and ureteral catheterization are practised in nearly every case of suspected renal disease, but it is our opinion that catheterization of the supposedly healthy side may do harm, and it is seldom if ever performed. The X-ray has rarely been of material assistance in determining the absence of calculi.

A history of the fatal nephrotomy in 1903 is as follows:

Case I.—Anuria; Stones in both Ureters; Nephrotomy; Uretero-lithotomy; Renal Decapsulation; Death.

Louis W., sixty-five years old, was admitted to the medical side of the hospital on September 3, 1903, for an illness which had begun ten days before, with severe left renal colic lasting five days and accompanied by dysuria with pain at the end of the penis. For the forty-eight hours previous to admission there had been complete suppression. There had been vomiting but no other uremic symptom. Two hours after admission a catheter was passed and two drops of urine were withdrawn. The microscope showed epithelial cells apparently from bladder and urethra but no renal elements. Treatment was instituted with salts, calomel, hot air bath, pilocarpin and subcutaneous infusion. This proving unsuccessful the patient was transferred the same day to the surgical side where under chloroform anesthesia Dr. Elsberg operated, decapsulating the right kidney and performing ureterotomy for a stone felt in the ureter of the left side. The ureteral opening was sutured, but a large tube was left in the renal pelvis passing through the substance of the kidney which had been previously incised with the hope of extracting the calculus by that route.

Pathological report of a section of the left kidney by Dr. Mandlebaum showed an acute inflammation upon a chronic nephritis. Except for the secretion of a urinous discharge into the packings of both wounds there was no relief. No urine was passed by the natural channel and the patient died four days after the operation.

Autopsy, by Dr. Mandlebaum, showed suppuration of the wounds with pyelitis and chronic nephritis. No peritonitis. Three small stones completely blocked the left ureter about 12 inches from the renal pelvis, and there was no marked change in the ureter at point of impaction.

The following unusual case was not diagnosticated even on operation and things were only cleared up at autopsy, cyst of the pancreas having been suspected.

Case II.—Cyst of the Kidney; Transperitoneal Incision and Drainage; Death.

J. S., fifty-five years old, was admitted July 26, 1903. He was a Russian, but had been living in Roumania, near the border, where swelling of the liver was a common complaint among the population. At home he had kept from two to five dogs about the house with which he and his family were in intimate contact. Syphilis and gonorrhea were denied. He said that he had had a swelling in his abdomen for months which gradually increased in size and that there had been an occasional lancinating pain relieved by hot applications or a bath. Four or five weeks before admission he had complained of severe pain in the mass, not radiating, and of local tenderness which had never been present before. There had been nausea and occasional vomiting. There had been neither fever nor chills. The bowels had been regular. There had been no urinary symptoms.

On examination there was a marked flatness in the fourth space in the midclavicular line, in the sixth space in the midaxillary and in the eighth space posteriorly. The lower border of the liver was palpable in the midclavicular line, 7 cm. below the free border of the ribs. On the left side 5 cm. below the free border of the ribs the liver was also palpable. There was no tenderness. Extending 18 cm. below the free border of the ribs within 4 cm. of the anterior superior spine of the ilium, and extending across the median line at its lower pole for 7 cm. and palpable 12 cm. below the free border on the left side there was a movable, irregular mass. About the center of this mass on the right side there was a smooth round prominence about 6 cm. in diameter, elevating the skin and acutely tender. The mass extended far back into the loin, dense, apparently fluctuating, and moving with respiration. A vibratory thrill could at times be made out. A cousin of this patient

had been operated upon by the writer some months before for echinococcus cyst of the liver.

Operation in the present case was done by Dr. Elsberg on July 28 under chloroform anesthesia. An incision about four inches long was made through the right rectus and extended upward and downward for a considerable distance. When the peritoneal cavity was opened a small amount of clear fluid escaped and a large cystic tumor moving freely with respiration and retroperitoneal in situation was seen. It was evidently not connected with the liver although it extended high up under its lower surface. The tumor consisted of a number of cysts many of which were opened, the contents being allowed to escape. As much of the walls as possible of the largest cysts was extirpated; the entire bulk removed being as large as a child's head. The edges of what remained of the tumor were sewn to the peritoneum. An attempt was made to empty the larger completely by wiping out with towels. During this procedure a mass was found in the right lumbar region. This was removed and proved to be a large calculus. The cavity of the cyst could not be entirely emptied and was packed with gauze. In one of the other cysts there was a small calculus the size of a pea. Mikulicz tampon and dressing were applied with suture of part of the wound. On the seventh day after the operation the cutaneous sutures were removed and on the eighth day the greater part of the wound was found wide open and the intestines exposed. Attempts were made to protect the general peritoneal cavity but without avail and the patient died on August 8.

The pathological report from the autopsy by Dr. Libman revealed a calculous hydronephrosis, general purulent peritonitis and infection of the sac wall. The fluid from the cyst showed serum, jaundiced, turbid, alkaline and of a specific gravity of 1.020. The fluid contained mucin, serum albumin and serum globulin, and gave a very strong peptone reaction. No sugar, no parapeptone, paramucin, ferments, or diastase. The microscopical examination showed many leucocytes, many red blood cells, few leucin crystals, no tyrosin or cholesterin and a faint trace of urea. The sac proved to be a hydronephrosis and showed no remnants of kidney tissue. It was adherent to the liver and head of the pancreas. The wall was trabeculated. The pancreas was negative. The left kidney showed evidences of parenchymatous degeneration.

Nephrectomy is performed by us as a primary procedure in cases of new growth, and in calculous disease when there are numerous stones scattered throughout the organ. A case of primary removal of the kidney for the rare condition of torsion of its pedicle appears on the list of recoveries. In cases of renal tuberculosis with great destruction of tissue primary nephrectomy has usually been done, but in other suppurative cases nephrotomy as a general thing has preceded removal. This gives the patient an opportunity to recover from the effects of sepsis due to bad drainage, so that his condition is more favorable for the severer operation. A kidney, too, which has been found greatly enlarged at the primary nephrotomy has not infrequently shrunk to one-third of its former size before the secondary nephrectomy. Another advantage in the two stage operation is that one may judge much better of the functionating power of the other kidney.

There were six cases of hypernephroma during the four years, intermittent hematuria being the prominent symptom in all. Secondary growths of this type, usually peritheliomatous, are apt to appear in the bones and in the liver. They often pulsate very strongly and in one case the tumor occurring, as it did, in the frontal region, exactly simulated an aneurism, pulsating with all the throbbing sensation of a true arterial dilatation.

Case III.—Stone in Ureter; Nephrolithotomy; Nephrectomy; Cure.

Max K., fifty-one years old, was admitted to the hospital on August 17, 1903, having suffered pain in the left lumbar region for one year. The history of his present illness covered five days. There had been acute onset, with lancinating pain, beginning posteriorly and radiating down the course of the ureter to the scrotum and penis. The attack had been accompanied by vomiting. There had been a chill at the onset, followed by fever. Urination frequent but scanty. When examined there was marked tenderness over the region of the left kidney and along the course of its ureter.

On August 18 Dr. Wiener operated under chloroform anesthesia. The kidney was exposed by the usual incision and was delivered with some difficulty. Palpation revealed a stone at the beginning of the ureter apparently impacted therein. An assistant compressing the renal vessels, an incision was made longitudinally into the kidney and through its cortex. The stone was felt at the mouth of the ureter. In attempting to extract it about one-half an inch of the ureter was torn away with it. No other stone could be found. During the course of manipulation the pelvis of the kidney was opened on its posterior aspect. An attempt was made to find the open end of the ureter with the idea of implanting it into the pelvis but it could not be found. The hole in the pelvis was sutured with catgut and the kidney sewn together with interrupted catgut sutures. The patient made a good recovery from the operation but the urinary fistula refused to close and, on October 13, the writer performed nephrectomy. The kidney was extremely adherent to the surrounding tissues and was delivered with great difficulty. It had contracted to about one-half its former size, and contained a marked amount of connective tissue. Convalescence was uneventful and the patient was discharged well, on November 28.

Case IV.—Perithelioma of the Kidney; Nephrectomy; Cure.

S. H., woman, fifty years old, was admitted on November 5, 1902. She was

married and had had six children and one abortion, her menopause having occurred one and a half years before admission. For three months she had noticed a marked loss of weight and general weakness without pain. There had been some difficulty in passing urine about four weeks before admission and the urination was accompanied by the passage of bright red blood and, for two days following, the urine was very dark in color. On two subsequent occasions she had passed old clots. One week before admission she had noticed a tumor in the left side of the abdomen. There were no disturbances of the bowels and no subjective symptoms by which the tumor could be localized. On admission she was found to be quite anemic and rather poorly nourished. The general physical examination was negative, but on reaching the abdomen a marked asymmetry was noted due to a huge tumor in the left flank reaching to the median line. This mass was fairly elliptical in shape and the long axis ran downward and inward. It had rounded edges and its surface was somewhat lobulated. It seemed to extend above the free border of the ribs. Posteriorly it went deeply into the lumbar region. It was readily balloted. Internally the mass reached well beyond the median line, the lower limit corresponding to the iliac crest. The colon was pushed inward. No intestine was felt in front of the tumor. The consistency of the tumor seemed solid and very hard.

On November 8, 1902, an oblique lumbar incision parallel with the ribs was made by the writer. It was found possible to push the peritoneum forward and deliver and remove the tumor together with the kidney, of which it formed a part. Partial suturing was done with silkworm gut and the immense cavity previously occupied by the tumor was filled with a Mikulicz tampon. The growth was the size of a large cocoanut, the surface irregularly nodular and its general consistency was much softer than was suspected from examination before the operation. There were numerous scattered cysts. The tumor mass on section had the characteristic yellowish granular appearances of hypernephroma. The growth seemed to spring from the entire convexity of the kidney. The pathological report by Dr. F. S. Mandlebaum showed perithelioma with necrosis. Convalescence was absolutely uneventful except that the silk ligature that had been used to ligate the pedicle *en masse* was rather slow to be given off. It came away January 7, 1903, two months after the operation and the patient was discharged well ten days later.

On November, 1903, no local recurrence but a pulsating tumor the size of a pigeon's egg was found in the left frontal region, having apparently eroded the bone over an area nearly as large as a silver quarter of a dollar. A full report of this case will be presented at its conclusion, but it should be here mentioned that incision and thorough curetting after ligation of the left common carotid showed the tumor to be a metastatic perithelioma.

Case V.—Hypernephroma; Nephrectomy; Death.

David S., fifty-two years old, entered the hospital on September 23, 1903. Had lost about 50 pounds in weight during the previous seven months. Had had frequent micturition with intermittent hematuria, considerable blood having been lost. On admission a large balottable somewhat irregular reniform mass was found in the left renal region, extending to within two inches of the median line. Left testicle somewhat enlarged. Operation September 26, by Dr. Wiener. Difficult nephrectomy owing to size of tumor and vascularity of capsule and adhesions. Peritoneum opened. The following day he died of shock and acute anemia. The specimen was of the size of an adult head. It had broken down into the renal pelvis. There was no autopsy.

Two histories of pyemic kidney abscesses follow. The complication of malignant diabetes contributed to the fatal termination in the second case.

Case VI.—Abscesses of Kidney; Nephrectomy; Cure.

Thomas S., aged twenty years, was admitted December 12, 1902. He had had furunculosis for a number of weeks before the onset of his present illness. About six weeks before admission he had complained of dull pain in the left lumbar region. The pain had been relieved by pressure. He also had had rigidity and tenderness in the right epigastric region which had ceased three weeks before admission. The pain in the left lumbar region had been intermittent, and at times very slight. He had begun to notice threads in his urine for the past three weeks. In urinating he had passed clear urine at first but later it had contained threads. He had had evening rise of temperature to 102.5° F. since the onset. The pain in the left lumbar region had been sufficiently severe to demand morphine. Blood examination had shown white blood cells 24,000, red blood cells 4,336,000, hemoglobin 82 per cent. He had been treated by Dr. Manges who sent him into the hospital.

On admission his general condition was found to be fair; he was much emaciated and had the appearance of an individual suffering from chronic sepsis. In the left lumbar region there was a slight fulness, dull on percussion, painful on pressure. On December 13 under nitrous oxide gas an incision into the mass was made by the writer and a considerable quantity of pus evacuated. A body supposed to be the kidney, could be vaguely felt through the wound. Drainage by tube. On December 15 an examination of the urine for tubercle bacilli was made but none found. The symptoms were not relieved by operation, therefore, on December 18, the writer performed a secondary nephrectomy for pyonephrosis and multiple kidney abscesses under gas and ether anesthesia. The twelfth rib had to be resected. It was necessary to perform the entire operation with great rapidity owing to the wretched condition of the patient. The pedicle

was clamped and tied off with heavy silk. The peritoneum was not injured. The kidney measured 8 x 6 x 4 inches. The external margin consisted of the remains of openings into numerous abscesses around the kidney. The external surface was congested, the consistency of the tissues being soft and fluctuating in areas. On section the parenchyma was found completely studded with multiple abscesses varying in size from a pinhead to a walnut. The pus was thick in consistency and creamy yellow in color. Most of the abscesses had distinct walls being sharply defined from the surrounding parenchyma. The pelvis was filled with pus. Many of the abscesses had broken into the pelvis leaving large sloughing ulcerations. The parenchyma of the kidney was pale, cloudy and its markings were almost entirely obscured. It was evidently in a state of advanced parenchymatous degeneration. The capsule was thickened but not adherent. Convalescence was steady and rapid. The ligatures were off on January 1, 1903. On January 19, one month after nephrectomy, he was discharged cured and has remained absolutely well ever since. The pus contained *Staphylococcus aureus.*

Case VII.—Pyemic Kidney Abscesses; Nephrectomy; Death.

Morris S., fifty years old, had suffered amputation of the thigh for diabetic gangrene on May 10, 1903. His recovery had been ideal, primary union having occurred. On June 25, however, after an illness of ten days he was readmitted suffering from symptoms of sepsis and with pain in the region of the right kidney. The urine was clear, containing a few pus cells demonstrated by the microscope. Two per cent. of sugar still present, but acetone and diacetic acid which had been present in large quantities had disappeared.

July 4 under nitrous oxide and ether nephrectomy was performed by the writer; a somewhat enlarged kidney filled with miliary abscesses being removed. The patient rallied from the operation but died of his sepsis four days later.

Case VIII.—Movable Kidney with Twisted Pedicle; Strangulation; Nephrectomy; Cure.

Esther C., aged sixty-five years, had had a sudden onset of pain in the right iliac region seven days before admission. There was frequent vomiting of food and bile. She had been constipated for three days. There was no elevation of temperature and no chills. She had passed about 30 ounces of urine each day, the urine being cloudy with sediment containing pus and few red blood cells but no casts. Her bowels were hard to move, the stools being green and small. She was admitted December 25 having been referred to the hospital by Dr. Hauswirth. Her general condition was poor. Her tongue was dry and coated. In the right lumbar region, above the iliac spine, there was a large, rounded mass, very tender on pressure, but obscured by the rigid contraction of the abdominal wall.

Having diagnosticated an acute surgical abdominal lesion probably connected with the kidney the writer operated at once, making a lumbar incision parallel to the iliac crest and about one and a half inches above it. The mass was aspirated and a small amount of pure blood drawn into the barrel. The perirenal fat was hard, friable and adherent to the peritoneum and abdominal wall. The tumor was found to be the kidney; hard, somewhat enlarged, with its pedicle twisted. It was freed and drawn into the wound. As the number of turns and their direction could not be determined, and as the organ looked much congested, a primary nephrectomy was performed, the pedicle being ligated with heavy silk. The ureter was tied separately with catgut. Through and through chromic gut sutures were employed except at the posterior portion where the skin was strapped. The kidney was somewhat enlarged, its surface dark and covered with hemorrhages. Upon section the cortex was found to be pale, edematous, containing no pus, and showing no dilatation of the pelvis. There were radiating streaks of yellowish pigmentation in the parenchyma of the kidney, where urinary salts had been deposited. The patient developed an hypostatic pneumonia from which, however, she made a good recovery. She was discharged on January 18, the ligature not yet detached; it came away a few weeks later.

Case IX.—Tuberculous Pyonephrosis; Nephrectomy; Death.

Solomon M., thirty-four years old, was admitted March 30, 1903. The family history threw no light upon the case. Had had gonorrhea fifteen years before. About a year ago, after an illness of three weeks with pain in the back, he had been told by his physician that there was pus in his urine.

About two months before admission he had gone through another illness with pain in the left side for about three weeks, then a disappearance of this pain and the occurrence of right-sided pain. About two weeks before admission the pain again became localized in the left side, leaving the right. No other symptoms had been present. Urination normal, four or five times a day. No chills or fever. General examination soon after admission was negative but the urine contained some albumin and a heavy deposit of pus. On April 9 the left ureter was catheterized and the urine examined. It contained a trace of albumin and a considerable amount of pus. On April 21 both ureters were catheterized. The flow from the right side could be markedly influenced by pressure bimanually in the lumbar region. It contained much more pus than that from the opposite kidney and tubercle bacilli were demonstrated in the sediment. April 23 tuberculin test gave positive reaction.

Operation by the writer on April 25, under chloroform. Adhesions were very dense all about the kidney. It became necessary to resect the twelfth rib, and the pleura was accidentally injured and had to be closed by suture. Nephrectomy was done, several inches of the thick gelat-

inous ureter being removed separately. The kidney was six inches long and three and one-half inches wide. It was slightly lobulated and fluctuated in places. Section showed three large discrete necrotic abscesses with many smaller ones.

The operation was performed at about 4 p.m. and at 7 o'clock the wound had to be reopened because of hemorrhage. No single bleeding vessel could be found but from the entire surface where the adhesions had been divided there was oozing, which could not be checked by packing and the patient died of acute anemia at six the next morning. Unfortunately there was no autopsy. The writer is certain that there was no bleeding from any spurting vessel.

DISEASES OF THE BLADDER.

Disease.	Operation.	Total.	Died.	Total, 1903	Died, 1903.
Cystitis	Suprapubic Cystotomy	9	0	1	0
Cystitis	Perineal Cystotomy	1	0	0	0
Vesical Hemorrhage	Suprapubic Cystotomy	1	0	1	0
Papilloma	Suprapubic Cystotomy	6	0	1	0
Calculus	Suprapubic Cystotomy	9	0	1	0
Calculus	Litholapaxy	1	0	0	0
Tumor	Suprapubic Cystotomy	2	1	0	0
Sarcoma of Bladder and Prostate with Peritonitis	Celiotomy	1	1	0	0
Retention	Suprapubic Cystotomy	1	0	0	0
Vesical Fistula	Cauterization	1	0	1	0
		27	2	5	0
Exploratory Suprapubic Cystotomy		1	0	0	0
Suprapubic Cystotomy in the Course of other operations		2	0	0	0
		3	0	0	0

It will be seen that there were 30 operations upon the bladder, in the four years, with two deaths, both in cases of malignant disease. During the year ending December 1, 1903, there were five operations without a death. But one of the cases operated upon during this year need be here reported in detail. The history follows:

Case X.—Vesical Calculus; Epicystotomy; Cure.

William N., aged eighty-two years, had been discharged after suprapubic prostatectomy performed on March 24, by Dr. Wiener. He was readmitted on October 9 with cystitis and frequent burning urination which had existed for about six weeks. On examination with a sound, which passed easily, a stone was discovered. On October 13 suprapubic cystotomy under nitrous oxide gas was done by the writer and a number of phosphatic calculi, about the size of large date seeds, were removed. It was then learned that, following the former operation, the nurse had for some reason neglected the irrigation of the bladder. On dissolving the calcareous matter of the stones with strong hydrochloric acid, nuclei consisting of bits of tough tissue were left. Convalescence was good and the patient was discharged entirely well on November 14.

DISEASES OF THE PROSTATE.

Disease.	Operation.	Total.	Died.	Total, 1903.	Died, 1903.
Abscess	Perineal Incision	6	0	0	0
Hypertrophy	Suprapubic Prostatectomy.	17	0	6	0
Hypertrophy	Prostatotomy (Bottini)	1	1	0	0
Carcinoma	Suprapubic Curetting	2	1	0	0
		26	2	6	0
Hypertrophy of Prostate. Urinary Sepsis	No operation	3	3	2	2

The total number of operations upon the prostate since December, 1889 was 26, and there were but two deaths; one after a suprapubic curetting for advanced carcinoma and the other, strangely enough, following a Bottini's galvanocaustic prostatotomy. In the last year there were but six operations upon the prostate and none of the patients died. All were suprapubic prostatectomies. We find the records of 17 of these operations during the four years and none of the patients died, all but one making perfect recoveries. The case which did not turn out well will be here reported.

(To be Continued.)

VESICAL RETENTION OF URINE.[1]

BY FERD. C. VALENTINE, M.D.,
AND
TERRY M. TOWNSEND, M.D.,
OF NEW YORK.

The single symptom of inability to entirely void the bladder contents, is so dispersed in literature that, when its prompt relief is imperatively demanded, text-book consultation is out of the question. The purpose of the present paper is to summarize the treatment of the symptom, with only so much allusion to its etiological factors as is necessary to decide upon the methods to be employed to relieve the emergency. The ends in view may be best subserved by first reciting the means ordinarily used.

Common Domestic Treatment.—In retention from any cause, provided that danger to life is not imminent, and provided also that the patient is

[1] Read before the Second Annual Meeting of the American Urological Association, New Orleans.

not too unmanageable for temporization (as during alcoholic inebriety) the ordinary domestic inciters to urination may prove successful. They are: (*a*) Exposing the patient to the sound of running water; (*b*) causing him to suddenly plunge one or both hands into cold water; (*c*) prolonged hot sitz-baths or general baths (*quod vide infra*).

If within fifteen minutes these fail, recourse must at once be had to catheterism. If consent to catheterize without general anesthesia is not obtainable, this must be employed.

Not infrequently the production of the emergency instruments induces a tendency to syncope, especially if glittering metal catheters are among them, and if these are not too noiselessly placed into the pan for resterilization, the promptly saturated condition of garments or bed will then show that the patient has been spared instrumental intervention.

Hot Baths.—When a patient cannot urinate, a prolonged hot hip or general bath suffices, in many cases, to overcome the retention. In all it gives time to inquire into its cause and to prepare for treatment. Furthermore, as all retentions resting upon disturbances of the urinary apparatus are aggravated by local congestion, the hot bath is useful in equalizing the circulation and thus tending to reduce the local congestion. Even if this is not sufficiently overcome to enable the patient to void urine, subsequent treatment will be easier in consequence.

The ten or fifteen minutes that the patient spends in the bath also give ample opportunity to prepare the instruments to evacuate the bladder, should they be required. At the same time the history of the case may be obtained and such physical examinations made as may be necessary. Among these, bimanual palpation, with one finger in the rectum and the fingers of the other hand on the prevesical region, will determine whether an enlarged prostate is at least a contributing cause of the retention. Experience in the rectal touch enables the practitioner also to very closely estimate the amount of urine retained in the bladder. This offers a most valuable means of differentiation, for if bimanual palpation shows the bladder to be empty, the absence of urination is not due to vesical retention, but to renal or ureteral retention, or anuria.

The bath, the examinations, the preparation of instruments often have decided psychic advantages. They appeal to the patient as active procedures directed to the relief of his distress. His quite natural anxiety and irritability are very much appeased and he is rendered a coadjutor in the manipulative measures that thereafter may be needed.

Obviously, however, if the physician is called when the retention menaces rupture of the bladder or urethra, immediate instrumental intervention is necessary, without the delay that the bath entails.

When the retention is due to general systemic disease (*e.g.*, typhoid fever, locomotor ataxia) it must be relieved by catheterism, although the hot bath may be of service incidentally.

Diuretics and Diluents.—Anything that increases the secretion of urine can but aggravate overdistention of the bladder. Therefore, diuretics and diluents are distinctly contraindicated in retention of urine.

Antispasmodics.—No retention of urine is ever caused by vesical spasm. Spasm of the compressor, however, can evoke temporary retention. But this retention is so brief that it subsides before any drug can take effect. It merits mention, if only to warn against the employment of antispasmodics to combat it.

Opiates.—These cannot affect a urinary retention, no matter what its cause. They may, however, retard the secretion of urine as they diminish all secretions, and thus delay the ever-increasing distention of acute retention. At the same time they must necessarily reduce the reflexes which are the essential stimuli to micturition. The caution with which they must be employed is, therefore, self-evident.

General Anesthesia may be serviceable under the exceptional circumstance of a hot bath being unobtainable. However, when complete retention is due to an obstruction (stricture, prostatism, a foreign body or growth) general anesthesia avails nothing, as it cannot reduce the obstruction. Neither can an anesthetic at all influence the pelvic congestion which may, when even a minor obstruction exists, precipitate a retention.

Other Devices.—The practitioner's ingenuity will oftentimes overcome an emergent retention. The senior writer of this paper recalls in connection herewith, a heavily strictured negro, who, after each alcoholic or sexual debauch, had retention. This patient had been taught by a physician, whose name he had forgotten, to cut a willow twig, render it smooth, and insert it into his urethra. By pressing it against the stricture, the congestion of the region was in a short time sufficiently reduced to enable him to emit urine.

A more directly effective procedure is related by Dr. Thomas R. Evans, of Ashland, Ky., in the *Philadelphia Medical Journal* of April 4, 1903. This author, speaking of another practitioner in citing a case of retention of urine, says: "He espied a castor-oil plant. The leaf of this plant gives a bend to the stalk like the curve of the male catheter. Its caliber, the fact that it is hollow, its ease of lubrication by slightly scraping it, and its comparative toughness all rendered it a natural catheter." Quotation of these instances is in no manner intended to recommend them as substitutes for careful, methodical, aseptic procedures. But when danger from the emergency is imminent and no proper means at hand to avert it aseptically, the risk of infection must be incurred to avert the more immediate menace.

Capital Surgical Intervention.—Whatever the condition that produced the retention of urine, major operation is only exceptionally required to meet the emergency. While in some cases capital operative measures may be needed to cure the

basic condition, the urgent symptom can in the vast majority of instances be relieved without life-endangering procedures.

Non-Operative Intervention.—The period for which a retention has persisted is no guide to the need of instrumental ingression. In some cases the alarm created by the inability to urinate is so great as to cause the secretion of immense quantities of hysterical urine, still further dilating the distended bladder, and consequently still further increasing the distress. Palpation and percussion, in many cases mere inspection, reveal an immensely dilated bladder, extending far above the pelvis and apparently on the verge of rupture. Rupture of the bladder, however, occurs but rarely, and can always be prevented by an operator who is prepared for the emergency. The preparation is so simple that even the youngest general practitioner who will observe the ordinary rules of asepsis, can carry to a successful issue every case, even when the most alarming symptoms present.

In order to render of practical value any effort to set forth the various modes of treatment of vesical retention that most uniformly prove successful, it must embody a consideration of the causes of retention. These are often so interlaced that any classification would be but artificial and hence non-conducive to an intelligent grasp of the subject. It seems better, therefore, to recite the conditions that may produce the symptom, in the order of their gravity.

1. *Retention Complicating General Diseases.*—Osler[1] says: "Retention of urine is an early symptom (of typhoid fever) and may be the cause of abdominal pain. It may recur throughout the attack." The same authority, in discussing locomotor ataxia, states: "The first warning of the disease which the patient has may be a certain difficulty in emptying the bladder."

2. *Simulated Retention.*—Some miserable creatures of both sexes feign retention of urine for the masturbatory gratification which catheterism brings them. Lydston,[2] in his classical work, calls attention to this as follows: "The gynecologist is compelled to be on his guard with reference to a not infrequent form of nymphomania, but one which is little suspected by those surrounding the patient, in which the woman develops a fondness for gynecological manipulations. The subterfuges and devices of such patients to induce handling of the sexual organs by the physician are often remarkable. One of the most frequent forms of this malingering is the pretence of retention of urine, although every disease that they ever heard of may be complained of by such patients in their insane endeavors to obtain manipulations at the hands of the physician."

Howe (quoted by Lydston) relates a case of this kind occurring under his observation at Bellevue Hospital:

"*Case.*—A girl, aged eighteen years, was admitted supposed to be suffering from retention of urine. She was thin, her eyes were deep-set but bright and staring, and were found filled with tears. Her statement was that she had passed no water for three days; that she was subject to these attacks and was treated by having her water drawn off. I introduced the catheter and found only a few ounces of urine in the bladder, not enough, indeed, to corroborate her history. The next morning, as she had not urinated during the night, I drew off the urine again. While doing so I noticed by a series of curious convulsive movements that she was under the influence of strong excitement. Further examination showed that the labia minora, clitoris and adjacent parts were red and swollen and bathed in a profuse mucous secretion. I then remembered that on the previous evening she had shown a somewhat similar state of excitement, and gave the nurse orders to watch her closely all day. In the evening the nurse informed me that the patient kept up a constant friction of the genitals when she supposed no one was watching, and even when eyes were on her she endeavored by uneasy movement in the bed to keep up the titillation. Knowing then what I had to deal with, the patient was given a sedative and told she must empty her bladder without assistance. For thirty-six hours subsequently she obstinately insisted on her inability to urinate. When she was told that no catheter would be employed again, there was no further retention. Soon after she left the hospital, I learned that a physician friend of mine was treating her for uterine disorder, but he, too, soon found out the true nature of the case, and advised her to get married."

"A number of cases of a similar nature have come under the author's observation, both in hospital experience and private practice."

Lydston's experience is not dissimilar from that of other specialists. The senior writer of this paper recalls a few males who used like subterfuges to the same end.

3. *Hysterical Retention of Urine.*—Detailed consideration and treatment of these cases, as those of simulated retention, belong in the domain of psychiatry.

4. *Retention from Delayed Urination.*—Only those cases in which no pathological change exists are intended to be covered under this paragraph. Some men and women, otherwise quite sensible regarding their physiological needs, will defer the act of urination in obedience to social demands, even when conveniences for relief are at hand, as in European cities. The first desire to urinate is easily controlled. Tolerance of increasing vesical distention is soon established, and for a while the desire to void the bladder ceases to assert itself. The conditions that then attract the patient's attention to any abnormality are, (*a*) a vague sensation of pelvic or abdominal discomfort; (*b*) recollection that an unusually long interval has elapsed since the last urination, or (*c*) an unsuccessful attempt to empty the bladder in obedience to habit, as before retiring.

[1] Osler. "The Principles and Practice of Medicine," Appleton, 1902.

[2] G. Frank Lydston. "Surgical Diseases of the Genito urinary Tract," F. A. Davis Co., 1899.

Ineffectual efforts to void urine under any of the above circumstances soon produce great physical and still greater mental distress. The patient unconsciously evokes the additional aid of the abdominal muscles to assist the detrusors in overcoming the compressor. The greater the efforts thus made, the more intense does the distress become. If long in this condition, the patient may appear to be on the verge of collapse, the pulse becomes small and rapid, respiration labored, the expression anxious, the skin pale and bathed with clammy sweat. In very rare cases syncope results, and when it does, the consequent muscular relaxation often allows the escape of urine. The sudden emptying of the bladder, in such an event, may be followed by hemorrhage *ex vacuo*, as is likely to occur also when retention due to other causes is too abruptly entirely relieved.

The treatment of retention due to delayed urination does not differ materially from that of retention dependent upon other causes, except that in the former, recourse to general anesthesia may be inevitable when the patient's pusillanimity precludes even touching the genitals.

5. *Retention from Excesses in Baccho et Venere.*—It occasionally happens that a person, of either sex, with normal urinary apparatus, is seized with retention of urine, while in an alcoholic or sexual debauch. The treatment of such a condition is identical with that of retention due to delayed urination (*supra*).

6. *Retention from Fear of Pain.*—Occasionally a case is seen in which the patient suppresses the desire to urinate because the preceding urination was painful to him. This ordinarily occurs with patients suffering from acute gonorrhea, who cannot be convinced that after an irrigation of the urethra, urination which previously was painful is most likely to be entirely easy and free from difficulty of any kind. A retention of this kind must be treated as retention in the beforementioned conditions.

7. *Retention Due to Stricture.*—When a urethral stricture is neglected, it generally contracts so gradually that the patient does not observe the reduction of the caliber of his stream. So, too, he fails to observe the gradual increase in the number of times he finds it necessary to empty his bladder. If uncleanly, he pays no heed to the dribbling of urine that follows micturition which, saturating the garments and macerating the epithelium of the genitals while it decomposes, may produce irritating skin eruptions. These, then, may cause him to seek advice leading to the discovery of the presence of urethral stricture. In some cases the stricture is not noticed until the patient, after an alcoholic or sexual debauch, suddenly finds himself unable to urinate. In rarer cases, without precipitating cause, the peristructural region becomes engorged until it entirely arrests normal emission of the vesical contents.

Whatever the cause that leads a stricture to prevent the extrusion of urine, the retention must be promptly conquered. This demands, primarily, every effort to traverse the urethra without the slightest injury to its mucosa. The first impulse of the inexperienced is to insert a small instrument. This is an error, because it invites the very injuries which it is essential to avoid. A fine catheter, no matter how soft, is more likely to engage in and penetrate the urethral folds or enlarged Morgagnian crypts, puncturing, tearing or producing false passages, which seriously complicate the condition. The rules to be observed are the following: (1) Wash the urethra as far as possible with hot boric acid 4 per cent. solution, or oxycyanide of mercury 1-5,000. (2) Select the largest blunt, soft rubber catheter that will pass the external meatus, lubricate it liberally with Gouley's saponic lubricant, Guyon's ointment, Synol soap, or 10 per cent. suspension of iodoform in glycerin. (3) If the catheter in its course toward the bladder is arrested, press it gently against the obstruction for a few seconds. If the obstruction does not yield to mild pressure, withdraw the catheter and select a smaller one. (4) In case three or four blunt catheters successively used prove futile, continuance of their employment is inadvisable, as they are likely to irritate and increase the urethral congestion. Therefore, it is well, at this stage, to have recourse to conical olivary woven catheters, whose high polish diminishes the risk of frictional injury of the mucosa. The same technic suggested above (3) is to be applied in the use of these catheters. (5) In case the conical olivary woven catheters also fail, several efforts may be made with the Delafosse or Phillip's rat-tail catheters. As the sudden obstruction met in the strictured region is usually soft tissue, it is most likely to yield to the very gradual increase of size of these catheters, after their fine terminals have traversed the coarctated region. (6) As soon as any of the above-mentioned instruments has entered the bladder, the urine will escape from its mouth. The relief that the patient then experiences might mislead one into allowing the entire vesical contents to escape. This would be a grave error, for two reasons (*a*) sudden evacuation of the bladder is likely to produce a serious hemorrhage *ex vacuo;* and (*b*) withdrawing the catheter after it has rested but a few moments in the strictured region, robs it of the opportunity to exercise that decongesting influence which must immediately precede the dilatations that are subsequently employed for treatment of the stricture.

Hence it is wise to relieve the bladder very gradually. This is best accomplished in the following manner: (1) Allow 60 c.c. of urine to escape. Save this for microscopical examination, so that it may be decided, as soon as possible, whether the upper urinary organs are affected. (2) With a syringe or irrigator, inject through the catheter 30 c.c. of warm 4 per cent. boric acid solution. (3) Permit 60 c.c. of the bladder contents to flow off. (4) Inject 30 c.c. of the boric acid solution. Continue the above procedure

until nothing but clear boric acid solution flows from the catheter.

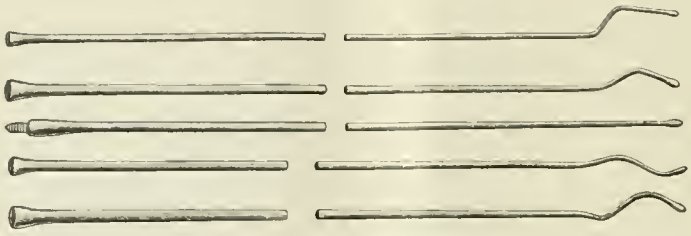
If, however, all efforts at catheterism fail, recourse must be had to filiform bougies. These are employed as follows: (1) Bend the ends of three filiforms in the shape of bayonets; bend three at various angles, and three into corkscrew terminals. Dip each one into collodion, which, on drying, maintains the instrument in the shape given it. (2) Take the penis in the left hand and, with a syringe, fill the urethra to its fullest capacity with iodoform 10 per cent. in glycerin. While holding the penis with the third, fourth and fifth left fingers against the left thenar eminence, compress the glans with the left thumb and index finger to prevent the iodoform-glycerin from escaping. (3) Insert into the urethra as many straight, angular and bayonet-shaped filiforms in equal numbers as the meatus will easily admit. Very gently guide them as far as they will go, without exercising any force whatever.

When the filiforms are arrested, select any one of them and advance it gently until it will not proceed further without the employment of more force than is required to project it. Repeat this procedure with each one of the filiforms successively until one of them has found its way through the coarctation and into the bladder. Then remove all the other filiforms and anchor this one in place according to Guyon's method, as elsewhere described.[1] (4) If the introduction of a straight, bayonet-shaped, or angular filiform is impossible, then insert a corkscrew filiform in the same manner as described above. When it has reached a spot which it will not traverse, turn it very gently to the right and left until it becomes engaged in the lumen of the stricture through which it will then readily find its way. Should it reach a point whereat its progress is definitely arrested, insert another corkscrew filiform and employ it in the same manner as the preceding one. In cases of excentric or tortuous stricture, three or four or more such filiforms may sometimes be needed.

When a filiform has traversed the stricture, even though tightly grasped by any part of the urethra, the retention is practically conquered. Drops of urine will soon begin to dribble along its sides and in from six to twenty-four hours the filiform will be found lying loosely within the stricture. A catheter can then be easily inserted. It will be well, when catheterism has become possible, to anchor fast the catheter in the same manner as the filiform was kept *in situ*, and to close its mouth with a wooden plug or spigot which may be removed at regular intervals and the bladder washed when necessary.

If examination of the urine reveals that the upper urinary organs are seriously affected, the presence of the filiform through the stricture will assist in establishing the drainage which is the condition precedent to treatment of the vesical, ureteral or renal involvement. Moreover, if rupture of the bladder, of the posterior urethra, or infection menaces the patient's life, then the filiform will serve to conduct a Gouley tunneled catheter for more rapid evacuation of the bladder or as a preliminary to internal urethrotomy or a guide to external urethrotomy.

Fig. 1.



Filiform bougies: Straight, angular, bent bayonet-shape and with cork-screw terminals.

Whenever all efforts to introduce even the finest filiform through the stricture prove unavailing *suprapubic puncture* may save the patient from a dangerous operation. This is performed by first shaving and rendering the pubis aseptic and then plunging a canula and trochar through Retzius' space into the bladder. This almost painless and safe operation may be repeated three or four times in twenty-four hours. Before each repetition, efforts should again be made to traverse the stricture as before suggested. In the vast majority of cases they will prove successful sooner or later, in consequence of the reduced congestion established by removal of the impediment which an overdistended bladder offers to return circulation.

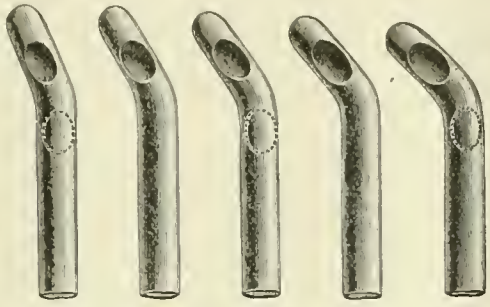
8. *Retention Due to Prostatic Enlargement.*—Prostatics are liable to retention of urine at any time, from the same causes that can produce retention in strictured patients. The symptoms of such retention are practically identical with those of retention caused by stricture. The treatment of this retention is not difficult while the bladder-contents are still aseptic. If the retention is recent, a prolonged very hot bath often procures relief without instrumentation. If, after ten or fifteen minutes of such a bath the patient cannot empty his bladder, his hips may, while he is still lying or sitting in hot water, be elevated sufficiently to expose the genitals for catheterism. The instruments most safely used are the Mercier

[1] "The Irrigation Treatment of Gonorrhea: Its Local Complications and Sequelae." Wm. Wood & Co., New York.

woven catheters as modified by Guyon. These catheters are made with their beaks bent at various angles, as shown in Fig. 2.

In the use of these prostatic catheters, the same rules obtain as given for the employment of filiforms in retention due to stricture, with the exceptions noted below: (1) If the urethra is not abnormally contracted at any point, the catheter is gently but steadily guided to the prostate. Then, together with the penis it is depressed between the thighs, so as to cause the catheter's beak to surmount the elevation of the prostate.

Fig. 2.



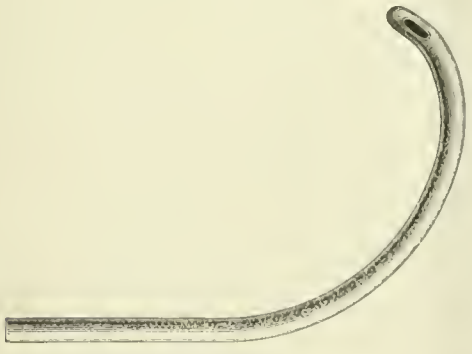
Guyon modification of Mercier catheters.

Fig. 3.

Double-curve catheter.

(2) When a catheter refuses to overcome the obstacle in this manner, it is prevented possibly, by the angle of its beak (see Fig. 2) being too small. One whose beak has the next larger angle is then used. This process is continued until a catheter selected overcomes the obstacle. In some cases

Fig. 4.



Metallic prostatic catheter.

double-curve catheters (Fig. 3) will be found necessary to attain the desired end.

In exceptional cases the metal prostatic catheters (Fig. 4) will be required. Their employment is demanded especially when severe spasm is associated with the retention, or when the condition is complicated by local disturbances.

In all cases, the bladder must be emptied *par etappes* (Guyon); *i.e.*, by the same gradual method advised for the relief of retention due to stricture. When the urine is aseptic, boric acid solution will suffice. When the urine is infected, solution of silver nitrate, 1 to 5,000 down to 1 to 2,000 or stronger, must be employed. When the urine is very turbid and putrid, resorcin 1 to 500 down to 1 to 100 often proves serviceable.

Retention due to prostatism may be complicated by a foul bladder produced by (1) cystitis due to decomposing residual urine, (2) infection from without, (3) infection from the upper urinary organs, (4) stone, (5) bleedings from the prostate or the bladder-walls, (6) intravesical growths.

Whenever any complication is present, or when catheterism is difficult, it is advisable to anchor the catheter in place as soon as the emergency is overcome.

According to the condition, the mouth of the catheter is plugged as advised in the treatment of retention due to stricture, or the bladder is continuously drained. The drainage by catheter is easiest of accomplishment by attaching a short rubber tube to the mouth of the catheter and resting its free end in the bottom of the narrow tube of a Du Chastelet urinal in which a tablet of mercuric bichloride is kept.

In some cases catheterism and drainage may be impossible, because of (*a*) immense prostatic enlargement, (*b*) irritability of the urethra, (*c*) unwillingness of the patient to submit to the necessary procedures, even when painlessly conducted.

Suprapubic puncture (see Retention due to Stricture) may then be employed to overcome the emergency. Frequent repetition of these punctures, when the bladder is infected, cannot be advised.

In any of the above conditions, or when membranous cystitis, stone, a growth, severe bleeding or menacing infection of the upper urinary organs exists, radical operation is required.

According to the condition, the intervention needed may be suprapubic or perineal drainage, galvano-incision of the prostate (Bottini) or complete prostatectomy.

Less frequent, yet occurring often enough to warrant mention here, are the following causes of vesical retention of urine:

9. *A Tight Meatus.*—This, especially in the newborn or in others, when any irritative condition causes the occlusion, may produce retention of urine. Its mere presence can also, by evoking that spasm of the compressor, described by Otis Sr., some thirty years ago, suffice to prevent extrusion of urine. The condition itself indicates the treatment—prompt meatotomy.

10. *A Tight Prepuce* for the same reasons may provoke spasm of the compressor. Immediate relief is obtained by at least slitting the foreskin, when the emergency is so urgent that there is not time for circumcision.

11. *Phimosis and Paraphimosis.*—Either of these conditions may be the direct cause of retention of urine, as they also may evoke that compressor-spasm which can prevent evacuation of the bladder.

12. *Severe Hyperacute Urethritis*, gonorrheal, chemic or traumatic, may cause such swelling of the mucosa as to render the urethra impassible for urine. Wossidlo[1] concisely disposes of such a sudden, complete retention by advising the use, at first, of narcotics and hot baths: "If these fail, catheterism must be employed. For this purpose a soft, well-sterilized, elastic (Nelaton) catheter is used, after carefully irrigating all that part of the urethra that may be accessible thereto, with a hot solution of potassium permanganate 1 to 4,000 and then anesthetizing the mucosa with cocaine or beta-eucaine."

13. *Foreign Bodies.*—These may occlude the urethra or so rest within the bladder as to obstruct the internal meatus. Such bodies may be produced within (*e.g.*, stone, blood-clots, thick, dense shreds of mucus) or may have been inserted for therapeutic purposes (*e.g.*, broken catheters) or with masturbatory intent. To what extent the last-mentioned psychic aberration may go, is well exemplified by some Crétins of the Alps. Among these people are found furious, persistent masturbators, who, when their ordinary means of self-gratification cease to be effective, insert twigs even beyond the compressor into the posterior urethra for the purpose of titillating the colliculus seminalis in order to produce an orgasm.

Occasionally a young female is seen who, in endeavoring to rid herself of the product of conception, tries to insert a catheter or crochet needle or other foreign body into the womb. Through ignorance and maladroitness she forces it into the bladder, where it may fall behind and occlude the internal meatus, besides provoking cystitis.

Even if a foreign body does not prevent urination, or does not produce very troublesome symptoms, its removal is imperatively indicated. When lodged in any part of the urethra, but not very firmly imbedded within its tissues, the foreign body is generally most easily removed with the aid of the urethroscope. When, however, the urethral caliber is too small for the introduction of a serviceable tube, efforts may be made to remove it with a urethral foreign-body forceps, guided by the sense of touch.

When the foreign body is wedged deeply in the posterior urethra and cannot be removed and is small enough to permit being so treated, the retention may be relieved by thrusting the foreign body backward into the bladder by means of a sound aided by a finger in the rectum. Of course, its removal from the bladder must be accomplished as soon thereafter as possible. Occasionally such a stone imbedded in the tissues of the perineal urethra cannot be dislodged by any of the means mentioned. Then it must be removed by perineal section. Guiteras[1] reports such a case, the stone thus removed by him probably being the largest on record as taken from this region.

A foreign body in the bladder requires removal, if small and soft by the Guyon brisepierre or the Nitze operating cystoscope. If large, litholapaxy, and if too hard for crushing, cystotomy will be required. If for any reason, an emergent retention due to a foreign body cannot be relieved by catheterism, the major operation indicated must be at once performed. It is unnecessary to add that the preceding is not offered as more than a very rough outline of the vast subject of foreign bodies in the urethra and bladder.

14. *Tumors* within the bladder or near it may preclude voiding urine. Ordinarily the emergency may be met by catheterism, or, when most exceptionally this cannot be accomplished, by suprapubic puncture. Naturally, the cause of the retention must be relieved by operative intervention as soon as the patient's condition permits.

A consideration of the sequelæ of retention of urine would carry us beyond the confines of this paper.

A cardinal rule, which in closing may be referred to, is that a patient with retention of urine must not be left until the retention is relieved.

It is but natural to inquire why an effort, at best but crudely sketching an isolated symptom, is presented before eminent genito-urinary specialists and in a program of deeply scientific, original papers. One justification therefor is advanced by our great master, Professor Guyon.[2] In connection with retention of urine, he says: "But when a morbid phenomenon acquires such an intensity that it not only disturbs a function, but renders it impossible, then, for this very reason it becomes a disease."

Again, it is hoped that this paper will be honored by a discussion. Such discussion will lend a value to the effort, which it could not otherwise attain.

Summary.—(1) When danger to life is not imminent, the domestic methods ordinarily employed may relieve the vesical retention, provided no mechanical obstacle exists. (2) Diuretics, diluents and antispasmodics are of no use in vesical retention of urine. (3) Opiates and general anesthesia are useful only under certain circumstances. (4) Capital surgical intervention may be necessary to cure the basic condition, but the urgent symptoms can, in most instances, be relieved without life-endangering procedures. (5) Even the youngest general practitioner can carry every case of vesical retention of urine to a successful issue. (6) The cause of the retention must in each case be ascertained. (7) Only most exceptionally does a case present which cannot be relieved by minor procedures. (8) No bladder should be suddenly entirely emptied because of the danger of hemorrhage *ex vacuo*.

THE DANGER OF THE USE OF OPIUM IN INFANCY.

BY T. D. CROTHERS, M.D.,
OF HARTFORD, CONN.:
SUPERINTENDENT WALNUT LODGE HOSPITAL, HARTFORD, CONN.

IN a recent text-book the author asserts that any form of opium discreetly given in small doses is safe and harmless in infancy, and that its action and effects are always transient. This seems so opposed to many facts and experiences that it is evident that the author was stating unsupported theories of the past. For years the bad effects and positive injuries to infants and children from the use of proprietary drugs and soothing syrups containing opium have been pointed out, until the danger seems beyond question. The various tinctures and infusions containing opium in some form depend for their popularity on the fact that they quiet irritation and pain, particularly from neurotic and nutrient disturbances.

In adult life opium and its alkaloids are usually depressants with a short period of excitation. This seems frequently to depend on the size of the dose, although it varies widely in many instances. From some peculiar condition of the organism opium may act as a sharp stimulant, that is, increase the heart's action producing wakefulness and exhilaration for a time, then merging into sleep and narcotism. In other instances this stimulant effect is very short, and the narcotic period comes on after the drug is taken, and is preceded by pleasing quietness, comfort, and then sleep. These two effects are very marked in some cases. Where children are given official doses producing increased excitement, with nervous twitching, then sleep and stupor it is evident that its action is very dangerous. In other instances under the same condition and doses, where profound sleep and stupor follow, there is great susceptibility to the narcotic action.

The physiological action of opium and its alkaloid are more pronounced in infancy and childhood than in later life. One reason for this is that the organism is more unstable at this period, and also because there is less resistance, and the drug makes a more profound impression on the sensory centers than later in life. Its sedative action is that of palsy, where the cell functions and the cells themselves are disturbed and diminished, and it is impossible to tell whether this checking may not become permanent, producing change and perversion that continues all through after life. The action of opium while apparently falling most heavily on the sensory centers extends to other neurons and functional states, and probably concentrates on that part of the brain most susceptible to its peculiar pathological action.

It is evident that coarse low organic natures, and imperfectly developed brains and bodies are less susceptible to the sedative effects of opium than those persons of high developed nervous organization. The higher the organism, the more pronounced the effect from smaller doses. The coarser the organism, other things being equal, the larger the dose required to secure its physiological action. These general facts are the same in infancy. A child who is very susceptible, and is relieved at once by very small doses illustrates one phase, and another child of the same age, who requires double the dose to secure narcotic action belongs to the other class. In both the resisting power is very feeble, and it is impossible to tell what organic changes may follow from the chemical and physiological action of any form of opium. And it is also difficult to decide whether the effects are transient in infancy and childhood, or whether each dose does not help to create a demand for its further use in the future.

In adult life the pleasing psychic effect from the action of a single dose calls for its repetition under like conditions. In infancy this same effect may be noticed in a child who has once been quieted by opium, in the unconscious manifestation of excitement which is only allayed by a repetition of the drug. This is clearly a pathological demand, and an ominous symptom of the danger from the use of opium where its effects are rapid and pleasing. Nursing children suffering from irritation, indigestion, and troubles incident to infancy have been quieted by opium taken by the mother, acting through the milk.

Opium-taking women have in this way permanently injured their children, retarding their growths, and leaving a defective organization which created a tendency to use some form of opium in after life. An instance of this kind occurred in the family of a noted missionary where three children were nursed by a Hindoo woman. Each one of them grew up with abnormal, highly sensitive brains and feeble power of resistance, and all became spirit and drug takers before middle life. It was ascertained that the nursing woman was an opium taker, and the poison of this drug was in some way transmitted to the children, permanently changing the nervous organizations and vigor. Another instance quite as startling, was that of a mother who gave large quantities of soothing syrup to two of her children in infancy, then becoming convinced of its danger, abandoned its use. These children in middle life, became neurotics, spirit and drug takers. Three children born later and not given any drugs in early life, grew up strong and healthy. The effects of the soothing syrup in infancy was undoubtedly the cause of the neurosis seen in the older children.

There can be no doubt that continuous sedation, or palsy of the sensory centers in early life is never repaired. The growth and development of other organs may do much to overcome this perversion and injury, but the defects remain, and appear in adult life in the feeble pain centers, and low power of resistance. In a family of five children whose parents were very healthy and strong, each one developed a neurosis and nervous disturbances that was unusual and without any visible cause. All seemed to have feeble

nervous systems, and to suffer from nutritional and nervous disorders, and were both irritable and dull at times, and all because spirit and drug takers. The mother had used laudanum in infancy for some functional disorders, and without the advice of a physician.

The presence of nervous dyspepsia beginning soon after puberty, and continuing for a few years, until some form of alcohol or opium is used is a hint of the use of opium in early life. Early and profound exhaustion from overwork or excitement, low vitality and feeble nervous resistance is a natural sequel to the use of opium in infancy. Defects and degeneracies which break out in early manhood suggest the same cause, and often follow from the use of soothing drugs given in infancy. A tendency to seek relief from every discomfort and pain, which may properly be called a neurotic diathesis, can be positively grown and cultivated by the use of opium in early life, although it it may not appear for years after.

The magnitude of this danger is not at present recognized. The routine and thoughtless prescription by the physician is often followed by grave disorders in later life. Opium by covering up the pain signals is not curative, but may be destructive in more ways than at present known, and this injury will only be recognized in the future. Too much caution cannot be given against the use of narcotics in infancy. Of these, opium is probably among the most dangerous, because it is so easily accessible, and its effects are apparently so simple.

WATER ANESTHESIA IN SURGERY, AND ITS SUGGESTIONS IN MEDICINE.

BY JOSEPH CLEMENTS, M.D.,
OF NUTLEY, N. J.:
MEMBER OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

This brief article cannot be better introduced than by a detailed description of an operation in which the above principle is illustrated. On February 4, 1904, I took a patient to Dr. Gant, of New York, to be operated on for "piles," a handful of them, always heretofore a hospital case of several weeks' duration. The doctor, however, did the work in the office by his new method, water anesthesia (see his article in the *New York Medical Journal*, January 2, 1904). No anesthetic was used, either general or local. The procedure was as follows:

Each "pile" was injected with distilled water, and at once emptied, clamped, tied and cut away, five being so removed in this instance. The operation occupied about fifteen minutes, and the patient, my nephew, returned home with me, walking to the trolley cars, ferryboat and train.

Another patient was treated, a tuberculous case. Under water anesthesia fistulæ were opened and scraped; another, deeper one, was found and the cutting and scraping were done without injection of water in this instance, but with such intense pain as to leave no doubt as to the reality of the anesthetic effect of the water, and the absence of any influence of suggestion, auto or otherwise. Several weeks earlier a "major" operation was performed, a laparotomy, in which eight inches of the colon were removed, with no other aid during the operation than the hypodermic injection of distilled water.

Now as to the anesthesia, caused, one may say *produced*, effectively and effectually, by the water, or rather the principle and explanation of it. Dr. Gant says that as soon as distention of the parts is secured, accompanied by blanching, anesthesia is attained and he proceeds to cut without fear of giving any pain, just as he would under ether or cocaine. The distention and blanching are of course merely mechanical; the question is, What is back of and beyond these? that is the secret, the effective agency in the phenomenon, the anesthesia? As I told Dr. Gant, after watching the operations, the water enters the interspaces of the tissues and fills them; the pressure of the distention causes rapid osmosis into the intracellular interspaces—for there are such between the granular appearing substance, the protoplasm—temporarily suspending intracellular respiration, which, like the beating of the heart is incessant, and thereby causing local "death," for the time being. The nerve centers being paralyzed no afferent impulse is sent, and no response in the central ganglion arises, and of course pain is impossible.

This is still too early for a mature expression of opinion on the case, but important enough as a basis of "research" into the nature of the phenomena. Now for the point to be made and illustrated by these facts, and the principle they embody. Nothing save distilled water was used in these cases, and scores of others I have since seen. Would it be correct to say that distilled water has medicinal or anesthetic "properties," a "sedative action," or the "power to prevent or remove pain"? This is said of cocaine, eucaine, morphine, etc. There is just as much of "curative" or other "property" in distilled water as in solutions of cocaine or any drug. In other words, there is none whatever. The "property," the therapeutic or whatever action arises, is protoplasmic. In the specific instance of anesthesia, in the cases referred to, the distention, the pressure was mechanical, and effective in the suppression of cell respiration. Here we have, what may be termed negative results in suppressed protoplasmic activities, forestalling the cellular and protoplasmic action which occasions pain. Upon the fact and principle of protoplasmic activity are to be interpreted all organic phenomena. On this alone all manipulation of the complex and multiplex processes involved in disease may be based and guided. In the exhibition of drugs in the so-called "cure" of disease, the first question is: What action will result? This is a point in chemistry; biochemistry if one choose, though not necessarily so, as yet.

The second question is: What response will accrue from the mechanical and the chemical action of the drug injected? "Ah! there's the rub." Of this, alas! we know so little! Medical literature is marred by misapplied use of terminology, and misnomer. Newspaper and trolley-car advertisements catch up, exaggerate and spread the error. "It works while you sleep." "It acts while you take it," and the deluded public pay the dollar for the package which is a "sure cure" for the disease from which the carefully worded description makes the reader feel as sure he is suffering. "What are we going to do about it?"

A NEW INSTRUMENT.[1]

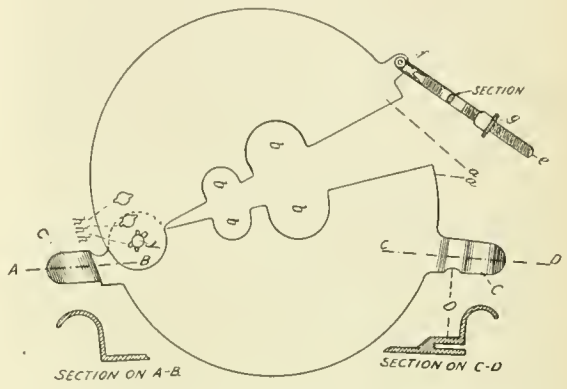
BY W. A. SEDWICK, M.D.,
OF PUEBLO, COL.

THE following is a description of an instrument for the protection of soft tissues when amputating and for hastening said operation, and which, for want of a better name, I have called an "amputation shield."

Description.—Two concavo-convex blades make the shield. There are two oval openings about the center, which openings are for the reception of one or two of the long bones. They may be enlarged or contracted at will, and either one may be enlarged or contracted proportionately greater than the other if desired, thereby giving practically any size, at the same time, of either of the openings or of both. One blade of shield has a male, and the other three female portions of a lock. This lock serves the double purpose of holding this end of the blades together, and aiding the regulation of the size of the openings. Corresponding with this, on the opposite side, is another lock, which has a tongue 8 to 9 cm. long, the upper and under surfaces of which have screw-threads, while the sides are smooth and flat. This is attached to one blade by a screw, and plays into a groove made for it on the other blade. A nut on the free end of the tongue, retains it in place as well as assists in regulating the size of the openings which receive the bones. The screw and nut are movable for cleaning. Attached to one blade are two supports or handles. On the proximal surface are the attachments for locks, etc., leaving the distal wholly smooth over its entire surface, with nothing to interfere in the application of a saw. Fig. 1 shows the instrument put together. Fig. 2 shows it applied.

Use.—It has been my privilege to use the instrument described several times, and to my entire satisfaction, and if it proves of the same benefit in the hands of other surgeons, it will, I hope, find a wide field of usefulness. We have all used the three-tailed bandage, gauze or towel, but I fear with very poor or only fair success. Retractors are not, I think, in general use. An assistant is not necessary to hold the shield, but to insure firmness, retraction, if necessary, and dexterity, he will not be superfluous. One of the openings—the smaller—may be entirely obliterated if desired, as for example, when there is but one bone involved, such as a humerus. It is not presumed that it will adapt itself to every inequality of the bones, but it will to the extent of preventing the protrusion of any of the soft tissues or flaps. The convexity is greatest at the point of application of saw, *i.e.*, at the point of the openings, thereby insuring free motion to the saw.

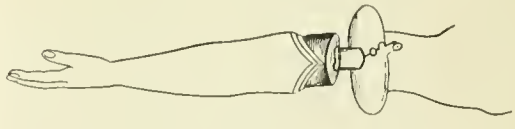
Fig. 1.



Concave surface: *aa*, blades of shield; *bb*, openings for bones; *cc*, supports or handles; *d*, groove in which tongue (*c*) plays; *f*, screw attaching tongue to blade; *g*, nut on free end of tongue; *hhh*, female, and *i*, male parts of lock.

Application.—After the flaps have been made and the periosteum well denuded and pushed back, open the instrument, apply around the bone or bones, retract to the point elected for amputation, throw the tongue into the groove and screw nut as tightly as practicable. There is then an absolutely clear, clean field. (See Fig. 2.)

Fig. 2.



Showing application and field ready for division of bone.

The following are some of its advantages:

1. It is easily made aseptic.
2. Easy of application, and quickly adjusted.
3. It protects absolutely the soft tissues or flaps.
4. It gives a clean, clear, non-obstructed view of the field of operation, and thereby saves what is often most valuable time.

[1] Read before San Juan (La Plata County) Medical Society, Jan. 8, 1904.

5. It is applicable to one or two bones, and to practically all parts of them.

6. It leaves a minimum of bone denuded of periosteum, which might possibly undergo necrosis.

MEDICAL PROGRESS.

MEDICINE.

Antistreptococcic Serum in Smallpox.—A series of cases of smallpox has recently been treated by injections of antistreptococcic serum with such good results that A. C. Smith (Med. Rec., April 2, 1904) believes that this method promises more success than any other. A full dose of twenty c.c. was used in each case and repeated in some of the severe ones. The advantages of this method were a shortening of the duration of the disease, absence of the secondary fever, lack of absorption of the septic products by prevention of pus formation, no pitting, no marked debility, less suffering and much less liability to lung and kidney involvement with a much more rapid convalescence.

Chronic Brass Poisoning.—One of the most confusing chapters in the domain of metallic intoxications is that relating to brass poisoning, and the varying opinions expressed in the literature would lead to the idea that there are no distinctive symptoms. H. N. Moyer and J. M. Lavin (Medicine, May, 1904) report a case which they believe is true brass workers' ague. The general symptoms are those of a chronic metallic poisoning, but differing from most metals in the development of chills, which are strikingly like but lack the ordinary periodicity of malarial ague. The green line on the gum serves to distinguish this from other metallic poisons, but it is not constantly present particularly in those who take good care of their teeth. The organic affections of the nervous system so common in other forms of metallic intoxication, are absent. The attacks are probably due to excessive ingestion of the metal, and most likely to the copper element in the alloy.

Organotherapy in Diseases of the Pancreas.—The successful administration of thyroid extract in diseases of that gland favors the supposition that a similarly good effect may be attained in disturbances of the pancreatic functions. K. Glaessner and J. Sigel (Berl. klin. Woch., April 25, 1904) have carefully studied the administration of various organic products in a series of cases where disease of the pancreas was believed to be present. Symptoms which were considered as characteristic included pancreatic colic and disturbances of metabolism and digestion, marked by the appearance of sugar in the urine, fatty stools and insufficient absorption of albuminoid materials. Among the various products which were tried they found that thyroidin exerted an unfavorable influence on the symptoms. Pancreon had little effect on the absorption of nitrogen and none at all on the fat. When pancreatin was used, however, the resorption of nitrogen was increased from 52 to 56 per cent., and the fat from 41 to 68 per cent. The most favorable results followed the administration at the same time of large doses of the alkaline carbonates, but the alkalin alone were not attended by any improvement. The best combination was a mixture of pancreatin and sodium bicarbonate.

Observations on Trichinosis.—Valuable additions to the knowledge of trichinosis is contained in an article by K. Schleip (Deutsch. Arch. f. klin. Med., Vol. 80, Nos. 1 and 2), who had occasion to study an extensive epidemic. The incubation was in general short, since many patients became ill the day after the infection, the remainder began to complain on the third to the eleventh day. Ofttimes the disease gave the general impression of typhoid and formerly great stress was laid upon the absence of enlargement of the spleen in trichinosis, but since the author could distinctly palpate the organ in almost every instance, other signs must be looked for. These are found in the blood, and a blood examination will always be of inestimable value in sporadic cases when trichinosis is not thought of. The amount of hemoglobin and the quantity and quality of the erythrocytes does not vary much from normal, the blood-platelets are considerably increased after the acute symptoms abate and there is generally a leucocytosis which rarely reaches 20,000. The greatest interest centers around the eosinophile cells, which are most abundant in the severest cases but almost always above normal. The highest figures obtained were 62.2 per cent., while in pemphigus only 33 per cent. has been reported, and in urticaria 60 per cent. It was impossible to ascertain how early the eosinophiles make their appearance, but since 44 per cent. was already found on the tenth day of the disease, the symptom is probably a very early one. The neutrophiles were generally diminished, the lymphocytes somewhat increased, especially during convalescence. Variations in the quality and staining properties of the cells were never noticed. The two diseases which are most likely to be confused with trichinosis are typhoid and polymyositis; in the former a blood-count will readily decide the diagnosis; while for the latter, records of blood examinations could not be found. In the affected muscles there are inflammatory changes, both of a parenchymatous and interstitial type, spread over all the fibers independent of the seat of the trichinæ, but in their immediate neighborhood there is, in addition, a well-marked granular degeneration. The capsule is surrounded by a wall of small round cells consisting of lymphocytes, connective tissue cells and a few polynuclear leucocytes; external to this infiltration, the degenerated muscle-fibers are very rich in eosinophiles, probably as a result of the chemotactic action of the toxins secreted by the parasite. Transitional stages between neutrophiles and eosinophiles were found in neither the tissues nor the blood, but occasionally the basophiles contained some distinct red granules.

Splenomedullary Leucemia.—The case of splenomedullary leucemia, which was recently reported by Dr. Nicholas Senn as being cured by the use of the Roentgen rays, has led to the report of two other cases which may be claimed as cures. B. L. Bryant and H. H. Crane (Med. Rec., April 9, 1904) employed both arsenic and the X-rays in the first case, and the latter means seemed to materially hasten the recovery. In the second case arsenic alone was used, and although the improvement was slow, it was nevertheless constant and permanent. In Dr. Senn's case arsenic was also used, so that it still seems doubtful how much of the benefit was really due to the X-rays.

Lysol Poisoning.—Though lysol is considered a harmless drug, some 38 cases of intoxication are reported, of which 17 were fatal. In some cases a single teaspoonful gave rise to alarming symptoms while in other cases recovery followed after 100 grains had been taken. A new case is reported by F. Fries (Münch. med. Woch., April 19, 1904), where the organ most affected was the kidney. The urine contained large numbers of casts covered with red blood cells, pigment and epithelial cells and as high as 12 promalbumin. Some of the casts were so large that they could be seen with the naked eye; their size and their branching make it probable that they originated in the collecting tubules near the pelvis. Their occlusion lead to uremic symptoms, which disappeared after a saline infusion.

DIGITALIS IN HEART DISEASE.

Notwithstanding the elaborate and painstaking studies of the physiological effects of digitalis that have been made, there is still no little doubt as to the exact indications which the drug can be expected to fulfil. The discussion of this subject last week at the meeting of the American Medical Association, in the Section on Medicine (see our Society Proceedings in this issue, page 1085) shows that there is at least a fairly definite agreement among prominent clinicians as to certain contraindications and some conclusive observations as to what type of heart disease it will benefit. It is unfortunate that to many physicians the word heart disease at once brings up the suggestion of the administration of digitalis. As a consequence of this false therapeutic nexus the assertion made during the discussion at Atlantic City that digitalis has probably done more harm than good, because of this lamentable tendency to use it in all cases of heart disease, once compensation is broken, would seem to have a certain amount of justification.

There is no doubt that digitalis employed in mitral regurgitation with symptoms of loss of compensation is often an extremely helpful and always a very satisfactory drug. On the other hand, any one who has seen the uncomfortable effects produced by digitalis in cases of aortic regurgitation, in young persons with hypertrophy of the left ventricle, especially where patients are still able and are allowed to be around on their feet, will realize how much harm may be done by its use in heart disease without proper selection of cases. It may be said at once that to suggest its use simply because there is a murmur present and because perhaps the patient is nervous as the result of having recently been informed by an insurance examiner or after some chance examination of the heart for some other reason, that he has heart disease, is almost sure to be harmful.

The typical cases in which digitalis does good, according to the consensus of those who took part in the discussion at Atlantic City, are those suffering from chronic mitral endocarditis due to rheumatism. In these cases, if both the aortic and the mitral valves have become affected, as sometimes happens, then digitalis does good notwithstanding the fact that in simple aortic regurgitation it is usually contraindicated. These cases, however, are seen typically in young persons, before there is any degeneration of arteries. Whenever there are sclerotic changes present in the arteries, as is typically the case in most instances when aortic disease develops, then digitalis is always contraindicated.

In stenotic conditions at the various valves digitalis would seem to be nearly always a dangerous drug. With regard to mild amounts of stenosis at the mitral valve there may be some doubt in the application of this as a general rule. In aortic stenosis, however, there can be no doubt, as the increased action of the left ventricle produced by digitalis when exerted in the direction of the already blocked path, through which all the blood in the body must pass about twice a minute, is sure to produce overdistention of the cavity with degenerative changes in the muscular fibers and dilatation rather than compensatory hypertrophy of the heart. When there is a considerable amount of stenosis of the mitral valves the same thing would seem to be true, since the auricular fibers are much less capable of hypertrophy for the purpose of overcoming the resistance that the blood stream encounters at this orifice. Some stenosis here, however, probably exists with every regurgitation and the indications are not so absolute.

In general it may be said, however, that the most important factor in any successful thera-

peutics of heart disease, whether it be by the use of digitalis or any other remedy, must always be considered to be absolute rest for the patient. It would seem especially unfortunate to use digitalis freely at times when patients are around on their feet and using practically all the strength they have when they should be resting quietly in bed and giving their hearts the indispensable opportunity to recuperate after the strain and the overwork which have caused the break in their compensation. It is the neglect of this precaution that, especially in the early and often quite tractable forms of mitral heart disease, is the true cause for complaints on the part of physicians of the failure of digitalis to give relief. There is another cause in the neglect of proper regulation of diet and due attention to intestinal evacuation which must be the first step in any treatment of heart conditions.

One of the greatest clinical teachers, here in America, once impressed this lesson upon his class by demonstrating a patient in whom both mitral and aortic regurgitation were present with, in addition, some leakage of the tricuspid valves. Heart compensation, which had at one time in the patient's history been quite satisfactory, was completely broken down. The Professor said, "You see how serious is this case. Of course we shall put him to bed and require him to rest there absolutely—that is, not allowing him even to sit up to eat or read. We shall make his diet as bland and as unirritating as possible and it shall consist mainly of milk, which fortunately he likes very well. We shall keep his bowels freely open and shall remove all sources of worry, as far as possible, from him. Of course we must give him medicine, otherwise he would be sure that nothing was being done for him. We shall prescribe for him ten drops of compound tincture of cardamom every two hours for the next week and I shall show him to you at the end of the week and you will see how much he has improved." The event justified his prophecy. The lesson was too precious ever to be forgotten.

NEW YORK'S OYSTERS AND TYPHOID FEVER.

It is now some years since it was absolutely demonstrated by careful investigations made in England and in this country that oysters may be an important means of transmitting typhoid fever. Notwithstanding this, there has been a general impression that while the occurrence of typhoid fever as the result of infectious material consumed with raw oysters did happen at rare intervals, it was very exceptional, and most people have gone right on eating oysters and other shellfish with only occasional times of carefulness—after some specially sensational announcements. If there are any left, however, who doubt of the possibility of the transmission of typhoid fever by means of oysters, such doubts would have been removed at a recent meeting of the Medical Society of the County of New York, held April 26, 1904.

The larger question emerges from this discussion, Why is it that typhoid is not more frequent when one considers the question from the infectious standpoint?

Dr. Bensel, the acting sanitary Superintendent of the Department of Health of New York City, gave a practical demonstration by lantern slides of the proximity of the beds where oysters are stored for fattening purposes to many sources of sewage material, human and animal, as from house drainage, the overflow from street drains and the like. The various oyster beds near New York were investigated, and practically the same conditions were found to exist in them all. On the Long Island shore of the Sound, on the Connecticut shore, in Staten Island, and on the Jersey coast, everywhere outhouses and barns are near the streams in which oysters are kept under water for days before being shipped to market.

After securing a load of oysters it is the usual rule of the dredger to bring them up some of the small streams where for several days they are put in the brackish water containing much less salt than that in which they lived during their growth. As the result of osmotic phenomena, the oyster, under these circumstances, absorbs and retains much more water than in its natural habitat. Thus the oyster acquires the fat succulent appearance which certain of the uninformed prefer, but which no true connoisseur in shellfish will ever accept as natural.

The fattening is carried on either on the lower floor of an oyster house, which is below the level of the water, at high tide, at least, or on the bottom of an oyster float; in tidal waters usually the houses are employed. In many cases, Dr. Bensel showed that within a few yards, indeed, often within only a few feet of these oyster houses, privies and cesspools were built and that sometimes the leakage from them surely would permeate the short distance to the bank of the stream, or even flow directly into the oyster house itself. Where the oyster floats are more common, as in Jersey, it is not unusual to find

that cesspools are erected in such a way as to allow the dejecta to find their way directly into the stream. In one instance, indeed, an oyster float was situated within a few yards of an outhouse used by a large number of people in a factory on the banks. Sewage of various kinds from the little towns finds its way into the small streams and, owing to the sluggish nature of the flow, because of tide-water below, this material readily finds its way into the oysterflats.

Another investigation of the New York Board of Health, under the direction of Dr. Cyrus Field, shows that ordinarily in salt water, typhoid bacilli will gradually die out, though for at least six days a number of virulent microorganisms remain. When oysters are stored in salt water then, there is not so much danger. In fresh water, however, the destruction of typhoid bacilli is not so rapid. Dr. Field also showed that in healthy oysters, the vital processes seem to protect the shellfish from becoming a mere culture medium for typhoid bacilli and that consequently there was at least no increase of the number of bacilli but on the contrary a gradual reduction in number. In oysters that are dead, however, or of lowered vitality, because of maltreatment during shipment, typhoid bacilli grow very rapidly. It would be natural to expect that oysters undergoing this fattening process in unclean water would therefore present a rather favorable condition for the growth of typhoid bacilli. They certainly are not so resistant as are healthy oysters.

It is very evident that a change will have to come, if the inhabitants of New York are to be protected properly from the dangers of typhoid fever. At one time, it seemed hopeless to think of protecting the city's milk supply. We have learned in recent years how much may be accomplished in this matter by care and insistence. The same amelioration of conditions must now be secured for the oyster traffic. The unhygienic process of fattening, unjustifiable from many points of view, must no longer be allowed or else must be conducted in perfectly clean water. This would not be difficult if, for instance, oysters were kept on the floor of a house through which was allowed to flow a stream of drinking water from the hydrant of a town known to have a good water supply. If necessary, salt may have to be added to such water in sufficient quantities to keep the oysters in a healthy condition. Certainly, with present surroundings, it is a wonder that there is not more typhoid fever, though many physicians have recently said that considering how fairly good our water is and the present supervision of our milk supply it is surprising to see how many cases of typhoid fever still occur. These announcements come at the end of the oyster season and it is to be hoped that measures for the proper protection of the oyster industry will be taken during these months without "R's," when the bivalve is not popular.

ECHOES AND NEWS.

NEW YORK.

Psychopathic Branch of New York Hospital.—Dr. S. B. Lyon, of Bloomingdale, has just revised and amended Dr. Pliny Earle's description of the old Bloomingdale Asylum in an attractive pamphlet.

Cornell University Medical College Commencement.—The Sixth Annual Commencement of the Cornell University Medical College was held in Carnegie Hall on Wednesday, June 8. Fifty-five students received their degree. Dr. W. W. Keen delivered the address of the evening. The ten students standing at the head of the class, counting the marks of all four years, were in order as follows: G. W. Cottis, Helen L. Carter, S. Feldman, C. A. Squires, E. N. Peck, W. Grossman, J. M. Goldberg, H. C. Becker, L. A. Parmenter and H. C. Gifford. G. W. Cottis, who stands at the head of the class, received a rating of 92 per cent. In addition to the money prizes to the first three of the ten a set of otological instruments was presented by Prof. Bacon for the best work in Otology during the year to Charles A. Squires, and a money prize by Dr. Dana for the best work in Neurology to C. L. Nichols. Dr. Austin Flint presented three prizes, each consisting of handsomely bound set of his own essays, to L. F. Schiff, of the second year class, and to G. W. Wheeler and L. L. Joshi, of the first year class, for the best work during the year in Physiology.

New Laboratory Building of New York University.—The council of the New York University, on the recommendation of the faculty of medicine, has arranged for the immediate erection of a six story edifice adjoining, and harmonizing in its architecture with the main college building. This will be completed and ready for occupancy with the opening of the college session of 1904-'05. It will furnish needed accommodations for the largely increasing number of students, and will render possible a further extension and elaboration of the laboratory work. The class room laboratories thus provided will be large and commodious, admirably lighted from two sides, and will afford exceptional facilities for teaching purposes. The first floor of the new building and part of the second will serve to increase the number of teaching rooms in the college clinic, which are greatly needed for the proper utilization of the 150,000 patients annually treated for clinical teaching. The remainder of the second floor will be used for the examination of specimens sent from the college clinic and from the medical and surgical services of the college in Bellevue Hospital. Students of the third and fourth year classes will have regularly assigned work in this laboratory, and will be thoroughly trained in the methods of clinical diagnosis. The third, fourth and fifth floors will be occupied by large class-room laboratories, devoted respectively to normal and pathological histology, bacteriology and applied pathology and chemistry. The

sixth floor will accommodate the increasing work in anatomy, experimental surgery and operative surgery on the cadaver. The removal of the class-room laboratories above-mentioned from the main college building will allow of immediate additions to the physiological and pharmacological laboratories and the pathological museum, and furnish greater facilities for research workers.

Epidemic of Meningitis.—The report of the Department of Health for the week ending May 28 shows that 80 deaths from cerebrospinal meningitis occurred here in the seven days, precisely 68 more than were reported in the corresponding week of 1903. Thirty deaths were of children under five years of age, 26 of children from five to fifteen years, 17 of persons between fifteen and twenty-five, and seven of persons between twenty-five and forty-five years. Last week the epidemic showed signs of abating.

Tuberculosis and the Health Board.—Pulmonary troubles have reached a maximum, says Dr. Darlington. One thousand cases are now under the direct care of the Health Department, the largest number on record. For the benefit of these sufferers and of the general community, Dr. Darlington has issued the following instructions:

"Be hopeful and cheerful. The disease may be cured, but it will take some time. Obey your physician's instructions faithfully; improvement may be lost by carelessness. Do not talk to any one about your disease, except your physician and nurse. Do not kiss any one upon the mouth. Shave your beard or wear it closely clipped. Stay in the open air as much as you can. Do not be afraid of cold weather; dust and smoke are worse for you than rain or snow. Keep at least one window open in your bedroom. Keep feet dry and warm. Avoid all unnecessary exertion. Never run or lift heavy weights. Never take any kind of walking, breathing or other exercise when you are tired, nor take them to the extent of getting tired. Go to bed early and sleep at least eight hours. Take a warm bath once a week. Take half an hour's rest on bed or reclining chair before and after the principal meal. Avoid eating when bodily or mentally tired or in a state of nervous excitement. Do not smoke or drink liquor, wine or beer, except by special permission, but drink plenty of good water between meals." The Department of Health is cooperating with Commissioner Woodbury in his war on foods that have been exposed to dust and germs. Dr. Woodbury's crusade against the exposure of food along the sidewalks or on outdoor stands will, if successful, drive the push carts out of existence and compel grocers and provision dealers to give up the display outside their shops.

New Medico-legal College.—St. John's College at Fordham will have medical and law departments added to its course of education, beginning with the fall term. They will be housed in a new building now in course of construction, and costing $125,000. It will be known as St. John's Hall. The Very Rev. Dr. J. J. Collins, the new rector of the college, said yesterday: "Formal application will be made to the State Board of Regents on June 27 for permission to have included in our curriculum the departments of law and medicine. While we have not been known as a university, our charter, obtained in 1846, is that of a university. Our name will be changed from St. John's College, Fordham, to St. John's University. We have been contemplating this increase of studies for some time, and have deemed it ripe for execution now. Especially is this so in the case of our medical department, since we are to have a public hospital on our grounds, four acres of which were purchased last week by the board of managers of the Bellevue and Allied Hospitals." "Are you to have the use of the hospital clinic?" Father Collins was asked. "We hope to have this courtesy extended to us. It has not, however, been mentioned by us to Dr. Brannan, nor was it stipulated in the sale of the property by us to them. Dr. Brannan assures us that the new hospital will be completed in about a year and a half, ground being broken for it in the next week or ten days."

PHILADELPHIA.

Official Guest of A. M. A.—Prof. A. Maitland Ramsay, M.D., of Glasgow, Scotland, the official guest of the American Medical Association was the guest of Dr. Charles A. Oliver of Philadelphia.

Physical Director for University.—Dr. R. Tait McKenzie, of McGill University, Montreal, has been appointed Director of Physical Education in the University of Pennsylvania. He will assume his duties at the beginning of the college year.

Red Light Treatment of Smallpox.—A pavilion has been constructed at the Municipal Hospital for the treatment of smallpox patients by red light. If the method proves advantageous, facilities for its use will be provided at the new hospital now in process of erection. For the first time in two years a week has passed without the report of a case of smallpox. Renewed efforts will be made to stamp out the disease during the summer.

Dedication of University of Pennsylvania Laboratories.—In the presence of an immense crowd of physicians from all parts of the United States, the new medical laboratories of the University of Pennsylvania were formally dedicated on Friday, June 10. Shortly before this hour a special train brought from Atlantic City some 800 of the visiting members of the American Medical Association as the guests of the University. Among them were such distinguished representatives of the profession abroad as Prof. Albert Hoffa, of Berlin; Dr. A. Maitland Ramsay, of Glasgow, and Dr. M. Miyushima, the representative of the Mikado of Japan, who is studying American methods of managing contagious diseases. Forming in line at Houston Hall the members of the faculty, headed by Provost Harrison, the alumni, and the guests marched to the steps of the new building. Here J. Vaughan Merrick, a trustee of the University, made the presentation address that formally gave the building to the University. He mentioned the great advances made by the University since it was removed to West Philadelphia thirty years ago. He said that the faith of the University in the highest ideals and its devotion to principles in seeking scientific truth and employing it in the service of humanity was embodied in the new building. Provost Harrison, in accepting the building, said he did so as a trust for the seeking of truth and the practical training of physicians. The University adds to her educational power the largest, best equipped, the most useful in interior plan and the most costly medical laboratory building yet erected, either in Europe or on the continent of America. He continued: "This great building bears no one person's name, and is the result of no single benefaction. It has been built up, rather, by numerous gifts, memorials and offerings, so that many hearts are turning toward this place to-day, and will rejoice with us all when I announce that no shadow of debt falls upon the new medical laboratories of the University of Pennsylvania." In the hall to be devoted to pathological histology the dedication speeches were delivered.

The Relation of Physiology to Medicine and Its Place in the Curriculum.—Dr. H. P. Bowditch, Professor of Physiology at Harvard University, who had been chosen to speak on the subject of physiology, said that the proper place of that branch would seem to be first as disease can be understood only when normal

functions are made plain. Anatomy demanded precedence, however, and the question is whether to place it first or give the two together. In Harvard the first three half years are devoted respectively to anatomy, physiology and pathology, an arrangement that has yielded favorable results. The greatest change in medical schools during the last ten or fifteen years has been the tendency toward laboratory instruction. This has been due to two reasons: (1) Medicine has followed the lead of chemistry and physics; (2) it has come as a reaction against too exclusive didactic teaching. The advantages are two, for power and for imparting information. What are the limits to this method of instruction? In the first place it is extremely costly. As an instance of this are certain experiments in metabolism if students are allowed to carry them through. Secondly, a considerable portion of the instruction must be given in didactic lectures. This brings up the question of how far didactic teaching trains the mental powers of the student. Dr. Bowditch believes that good lectures are a mental stimulus; they partially unfold a subject and invite thought on the questions involved. Recitations are even better than lectures as a means of instruction. Hence it can be seen that the laboratory has no monopoly on instruction. As to the relation of laboratory and lecture, the subject must largely determine this. In some, as nerve-muscle preparations, circulation of the blood, etc., the laboratory may be given first; in others, as metabolism and kindred subjects, lectures should precede the practical work. The reaction against didactic instruction is a good thing but in our enthusiasm we must not let the good things of former times be swept away.

Physiological Chemistry and Its Medical Value.—Dr. R. H. Chittenden, Professor of Physiological Chemistry at Yale University, said that laboratories are a true demonstration that medicine is an exact science. Under proper leaders they are a revelation to students and an inspiration for further investigation. The student here becomes confident; he proves things for himself and no longer has to take the mere words of a text-book. He is helped toward the freedom of mental supremacy. To those with exceptional minds they provide the means for the greatest discoveries. The laboratories being dedicated are a gain to the whole world as well as to the University. Medicine is two-faced; it is an empiric and it is a scientist. Real knowledge is a safeguard against quackery. Among the exact sciences physiological chemistry is one of the greatest and is destined to play an important part in medical education. There can be no clear or profound knowledge of pathology until the normal is comprehended and some phase of physiological chemistry is coming up at every turn. Dr. Chittenden then review in some detail the valuable results coming from the leadership and inspiration of Hoppe-Seyler in the laboratory of Strasburg. These illustrations he used to indicate the enormous latent power in a laboratory and to show the intimate relation between physiological chemistry and medicine; in the development of medical education the former will assume a more and more conspicuous position.

Pathological Anatomy.—Dr. George Dock, Professor of Medicine in the University of Michigan, a former teacher of pathology, spoke upon that phase of laboratory teaching. He traced the advance of that branch from its inception and referred to its brilliant future. He pleads for the further study of pathological anatomy by the student of clinical medicine. It is the bridge between the fundamental sciences and medicine. Practical teaching and laboratory methods are the topics of the day but they require material and time; the student's time in them is too short, but this should be arranged as well as possible. Sufficient teachers should also be furnished to properly handle the students and they should be trained teachers. The teacher should be also an investigator; his three qualifications are proper exertion, frequent exertion, and successful exertion. There are at present many demands for research workers alone but it is a pernicious idea that research work can be done only by hermits. Endowments to teaching laboratories are often of more value than to those for research alone. The idea that research work cannot be done by teachers is refuted by numerous brilliant examples. The same idea applies to hospitals; research hospitals are not necessary, though the means for research by the residents and staff ought to be furnished. The popular method is to furnish teachers with a number of "fellows." It is often better to give an overworked teacher a ten-dollar-a-week assistant than a "fellow" or two at a thousand a year. The neglect of pathological anatomy in the way of autopsies is a source of constant regret. An instance of this was in the war with Spain, where a half dozen autopsies would have soon settled the question of typhoid fever in doubtful epidemics. Large sums were spent for instruments to treat wounds that never came, while some of the largest hospitals did not possess a single autopsy instrument.

The Development of Laboratory Instruction in the University.—The storm of applause that greeted Dr. Horatio C. Wood, as he rose to speak, after being introduced by Dean Frazier as "the father of modern experimental therapeutics," must have warmed the heart of that veteran teacher who has given thirty-eight years of his life to the University. Dr. Wood briefly portrayed the development of laboratory instruction in the University from its inception. The term laboratory is often misused; in the older sense it means a place where experiments are performed. The first laboratory employed by Dr. Wood was the yard or stable of his uncle, Dr. Geo. B. Wood, and his instruments were made by himself or by a tinsmith. But here were performed experiments leading to conclusions that have never been disproved. Here was made the first investigation of a human disease upon animals ever undertaken and the results published in 1870, on thermic fever, are still classic. Little by little his laboratory facilities have grown since he was made Professor of Therapeutics in 1876, when he was given a janitor's room for that purpose, until the present magnificent quarters mark the climax. Of late years the word laboratory also means a workshop where students are taught. It is the only method for studying certain branches. The power of using delicate scientific instruments and noting the results is a great achievement. Dr. Wood made emphatic the point that though laboratories are essential, to the end the *man* is the important factor in teaching. One danger of modern laboratories is loading the man in charge with too much teaching. This can be averted only by properly increasing the teaching staff. In this way laboratories increase the expense of instruction. Endowments are now needed for medical as well as for other institutions; better a small laboratory with a large endowment than a large laboratory with a small endowment. Physicians are at fault in not securing money for our institutions; they fail to make known to the public the needs of—not ourselves but the people.

Inspection of the Laboratories.—Following the dedicatory addresses, the laboratories of physiology, pathology and pharmacology, which make up the new building, were thrown open for inspection by the visiting physicians. They have been described at length in a previous letter and detailed description is not now necessary. They are ready for occupancy, with the exception of installing instruments and other working paraphernalia. Pathological and physiological exhibits had been

arranged in many of the rooms for inspection. Only one opinion was heard from the inspecting guests: that for size, completeness and adaptability the new building excels anything heretofore attempted. After the inspection of the laboratory a collation was served at Houston Hall and at 10 P.M. the special train bore those who so desired back to Atlantic City.

CHICAGO.

The President of American Academy of Medicine.—Dr. Winfield Scott Hall, of Chicago, who has been elected President of the American Academy of Medicine, is the second Western man to receive that honor in twenty years. He has been professor of physiology in Northwestern University Medical School, this city, since 1895. He was born in Batavia, Ill., in 1861, and was educated at Northwestern and Leipzig Universities. He is a member of the Chicago Academy of Sciences and of other scientific and medical organizations, and is President of the American Medical Temperance Association.

Explanation of Chicago's Low Death Rate.—The low death rate of this city, which is fully two persons to the thousand less than that of New York, Philadelphia, Boston, St. Louis, or Baltimore, will be shown in all its bearings at the World's Fair at St. Louis. Health Commissioner Reynolds, of Chicago, will install the exhibit personally. It consists of a series of thirty charts, showing facts by comparative lines, four volumes giving blanks used by the department, photographs of the public baths and bathing beaches, and of the isolation hospital, and views showing the laboratory outfits for diagnosing diphtheria, pneumonia and other diseases. Assistant Commissioner F. W. Reilly, who prepared most of the exhibit, said: "Chicago reached its present low death rate by raising itself from the swamps, building a sewer system and introducing lake water from points as far as possible distant from pollution. It has cost the city $100,000,000 to do it. From a death rate of 73 to 1,000 in 1854, the rate has sunk to 15.43 in 1903, and it would have been barely 15 last year except for the Iroquois Theatre disaster." The chief gain has been in the rate affecting children under five years of age. This is closely associated with the department's inspection of milk and prosecution of offenders. The chart diagrams show that the following diseases are extinct or are diminishing in Chicago: Asiatic cholera, consumption, croup, diphtheria, measles, scarlet fever, typhoid fever, typhus fever, and whooping-cough.

Offer to State University of Harvey Medical College.—The University of Illinois may absorb the Harvey Medical College. A proposition has been made to the university that this school be turned over to it, as was the College of Pharmacy a few years ago, free of indebtedness. The President of Harvey College, Dr. Frances Dickinson, says the proposition was made to the Committee on Pharmacy, which was in session here about two months ago, and it is now under consideration by the medical committee of the University. Harvey College has been in existence for ten years, and during that time it has graduated twelve hundred students. Only 150 of these were full term students, as the school is maintained for persons over twenty-one years of age, who desire to take special courses in evening studies.

Some Practical Points on Adenoids and Adenoid Operation.—At a recent meeting of the North Shore Branch of the Chicago Medical Society, Dr. E. F. Snydacker read a paper with this title, in which he said that the diagnosis of adenoids should never be made on symptoms alone; before operation was performed, adenoids should be seen or felt. It was by no means necessary to operate every case of adenoids. Often symptoms attributed to adenoids were due to dyscrasia, of which adenoids themselves were only a manifestation. When the child was under improper hygienic conditions, adenoids become enlarged and symptoms aggravated; by improving the child's physical condition, the need of operation was often obviated. As the child developed, and nose and pharynx became more roomy, adenoids also becoming smaller, the child very often got along nicely without operation. There was often no great urgency for operation in such cases; it was always best to await the effects of hygienic measures and development. Different methods of operation were matters of personal choice; an anesthetic, however, was always advisable, otherwise the operator could not be sure that all the growths had been removed. Recurrence of adenoids often was a euphemism for improperly removed adenoids. No child would submit to an operation, and allow the operator to investigate result, and, if necessary, do more, unless methods were used little short of brutal; therefore, an anesthetic was to be preferred. At times, adenoid operations were performed where the walls of the pharynx were merely scratched, blood gushed from the nose and mouth, but the offending body was not produced. After an adenoid operation the adenoids which had been removed should always be found. Before operation it was well to locate the growths and choose the instrument according to the nature of the growths. The only after-treatment was to keep the patient quiet, in a room free from dust. The only complication was acute otitis media. The danger of this complication was lessened by following the course outlined above.

Offer of Hahnemann Medical College to State University.—Hahnemann Medical College has also made application for affiliation with the State University, and hopes for a favorable answer at the present session of the Board of Trustees. This is a homeopathic college. Dr. George F. Shears, President, says that the purpose of the request is purely a scholastic one, as they want the privilege of a great university for their students.

Tuberculosis of the Nervous System.—Dr. Julius Grinker read a paper on this subject at a recent meeting of the Chicago Medical Society, in which he said that tuberculosis of the nervous system is almost always secondary to tuberculous disease in some other organ. Brain tuberculosis occurs either as an affection of its membranes or in the form of the so-called solitary tubercle. Of all tumors of the brain, tuberculous tumors constitute the great majority, and occur with greatest frequency in childhood. Their place of predilection is the posterior fossa. The symptoms of tuberculous tumors are the same as those of other varieties. As differential points might be given the tendency of tuberculous tumors to locate in the posterior fossa, to remain latent for long times, to appear multiple, to have remissions in the symptoms. A localizing meningitis cannot be differentiated from a small tumor.

CANADA.

Convocation at McGill University.—On the afternoon of June 10 the annual convocation of the Faculty of Medicine of McGill University was held in Windsor Hall, when Dr. T. G. Roddick, M.P., the Dean of the Faculty, presided. In addition to the presentation of prizes and medals won by the students in the various years, the conferring of degrees, the presentation of diplomas and Board of Health certificates, the degree of LL.D. was conferred upon Dr. Trudeau, of Saranac Lake, N. Y., in recognition of his services in medicine generally. Dean Roddick delivered the annual address, the farewell address to the students and incidentally

Dr. J. T. Halsey delivered his farewell address, as he has resigned from the staff of McGill and has returned home to New Orleans, to take a position on the staff of Tulane University. The students' valedictory was delivered by Dr. Robertson of the graduating year.

Fifth Year in Medicine in Ontario.—A change is desired by the Queen's Medical Faculty in the regulation of the Ontario Medical Council regarding the fifth year work at medical colleges. At present only students who get positions are exempt from the special fifth year course of lectures and demonstration. Queen's desires that this be changed and that any medical graduate be entitled to try the final council examination who has been a house surgeon for a year, or has served a year with a qualified practitioner, or has attended clinics in a recognized hospital for at least a year.

Convocation at Toronto University.—The annual convocation for degrees in arts, science and medicine was held on the afternoon of June 10 in the gymnasium of Toronto University. In the evening the Chancellor, Chief Justice Sir William Ralph Meredith addressed the annual gathering of the alumni of the University. He said that during the past session there had been in attendance in all faculties of the University 2,135 students, and of this number the medical faculty had furnished 721. Next year he thought that they might expect an attendance of 2,500. Reverting to the federation of the medical faculties of Toronto and Trinity, the Chancellor said that it had proved an unqualified success, and it was satisfactory that in a faculty of 90 members there was no friction. He congratulated the medical faculty on establishing a post-graduate course, at which there is now in attendance from different points in the province of Ontario about thirty practitioners. He also commended the course in public health, which the faculty will soon establish.

Medical Appointments at the Hospitals of Montreal.—The Board of Management of the Montreal General Hospital have made several changes in the medical staff of that institution. Drs. F. S. Patch and C. W. Anderson are the only members of the present staff who will remain for another year. Dr. R. P. Campbell, who was formerly attached to the house staff of the hospital and who is at present in Germany, will succeed Dr. W. G. Turner as medical superintendent. Dr. Turner has left on a visit to England and Germany, and in the meantime the duties of medical superintendent are being discharged by Dr. R. C. Patterson. The new members of the house staff who will commence their duties in September are as follows: Dr. R. D. Forbes, anesthetist; Drs. J. L. Robinson, J. C. Fysche, W. G. Ricker, J. A. Nutter, L. L. Reford, H. H. Kerr, H. G. Wood, physicians; Drs. A. C. Rankin and W. E. Ainley, locum tenens. The Governors of the Royal Victoria Hospital have made the following appointments to the resident medical staff for the ensuing year: Admitting officer, Dr. R. King; Physicians, Drs. R. Hardisty, D. McKechnie, J. C. Meakins, W. A. Lincoln; Surgeons, Drs. H. Church, F. McKenty, J. Coffin, J. A. Faulkner, D. C. Maclachlan; eye and ear, Dr. L. C. Lauchland; nose and throat, Dr. H. O. Howitt; gynecologist, Dr. J. Gorster; anesthetist, Dr. F. D. Charman; locum tenens in medicine, Dr. J. E. Gillis; in surgery, Dr. J. W. Hutchinson; externe in medicine, Dr. J. R. Rogers.

The Prevention of Tuberculosis in Montreal.—The Executive Council of the Montreal League for the Prevention of Tuberculosis is a progressive body and it is quite possible that Montreal is doing more in the way of looking after her tuberculous than any other place in Canada. In order that every detail may be properly looked after the Executive has recently appointed several small special committees. There will be the Dispensary Committee, having for its object the establishment of a dispensary to be operated at the outset in conjunction with the general work of the League. Alderman Ames, a progressive sanitarian, is at the head of this committee, and associated with him are Drs. Dube and Finley. The Sanitarium Committee is another having for its object the establishment of one or more institutions to provide accommodation for the incurable as well as the curable cases of the disease. Mayor Laporte is at the head of this committee, and he has associated with him Dr. E. G. Daganais and Dr. A. J. Richer. A third committee is the legislative committee, having for its object the obtaining of legislative measures from the municipal and provincial governing bodies, so as to secure improved sanitation in schools, factories, etc., as well as obtaining power to enforce the notification of advanced cases of tuberculosis, the disinfection of places after death and the enforcement of the anti-spitting by-laws. On this committee are Dr. E. Pelletier, secretary of the provincial Board of Health, and Dr. Laberge, M.H.O., Montreal. The fourth important committee is the Royal Commission Committee for the purpose of urging on the Federal Government the advisability of appointing a Royal Commission, composed of not more than five members, to study the scientific and social aspects of the tuberculosis problem, and also the best methods to be adopted in this country for staying the progress of the disease. Dr. E. P. Lachapelle and Dr. T. G. Roddick will be the medical members of this committee. Thus it will be seen that the Montreal League is fighting the battle against tuberculosis in a systematic manner, which will be sure to be effective and productive of the very best results.

GENERAL.

Fourth Pan-American Medical Congress.—The next meeting of the Pan-American Congress will be held in Panama the latter part of December. The Pan-American Congress meets every three years. It was started by Dr. William Pepper, of Philadelphia, Dr. C. A. L. Reed, of Cincinnati, Dr. Albert Vander Veer, of Albany, and Dr. H. L. E. Johnson, of Washington. The first meeting was held in Washington in September, 1893, the second in Mexico in 1896. The third was to have been held in Venezuela in 1899, but was given up on account of the war in that country. The place of meeting was changed to Cuba, but had to be postponed until 1901 on account of the fever there. These meetings have always been well attended, and it is thought that Panama will be an interesting place for the convention. Further particulars will be sent out from time to time to the journals, together with notifications of the different officers appointed to represent this and other countries.

Yellow Fever.—Dr. Edward Souchon, president of the Louisiana State Board of Health, is in Washington in consultation with Surgeon-General Wyman and other renowned sanitarians. He does not consider the yellow fever problem settled. The excellent system of maritime quarantine and inspection, has prevented its ingress, but there has got to be an equally good system of land quarantine if we are to avoid danger from Mexico. A long frontier with only a shallow river to cross facilitates the spread of fever from that country. At the present time the disease has made its appearance in one or two Mexican localities. Curiously enough, too, the time of the appearance of yellow fever has changed considerably. Some years ago it was customary for it to show in May or June, but latterly it is as apt to manifest itself in August or September.

The Exhibits at Atlantic City.—To those who remembered the orderly and well-arranged exhibit of drug

manufacturers, publishers, instrument makers, etc., at Saratoga year before last and the excellent showing made at New Orleans last year, the exhibit this year was far from being satisfactory or up to the standard. It was badly arranged, inordinately crowded and not as representative as in the few years past. Some of the most representative drug firms had no exhibit at all, and even those who were there were too crowded to make an adequate showing. There is unquestionably a function of much importance in these exhibits. Particularly valuable is it to see the recent instruments, new forms of electrical appliances, new vibratory machines, new books, and even new remedies, if non-secret in their composition. A few features of special interest attracted our attention. The excellent showing of sick-room apparatus, by Meinecke, bed pads, etc., suggest that the Association authorities could encourage an extension of this type of advertising. The goods shown are useful to the physician and appreciated by the patient. In this line an ingenious commode bed was exhibited by a Dr. Heatley, of Glasgow. It was so arranged that a patient confined to bed did not have to move from a commode that was mechanically put in place beneath him. It seems worth trying, so that the limits of its usefulness may be determined. The various forms of vibration apparatus were objects of much attention. They merit careful examination, for vibratory massage has come to stay in therapeutics. Moreover our patients demand that the physician shall *do* something for them—other than give them drugs. The electrical exhibits were not as extensive as in former years.

Dr. Rush Statue Unveiled.—A bronze statue of Dr. Benjamin Rush, the noted Pennsylvania physician, philanthropist and patriot, presented to the United States Government by the American Medical Association, was formally unveiled last Saturday on the grounds of the Naval Medical Museum and accepted by President Roosevelt. Many members of the American Medical Association were present, as were also members of the Cabinet and other officials. Dr. J. C. Wilson, of Philadelphia, on behalf of the association, delivered a fitting tribute to Dr. Rush. In his speech of acceptance President Roosevelt said in part: "I accept, on behalf of the nation, the gift so befittingly bestowed by one of the great professions—this statue of a man who was eminent not only in that profession, but eminent in his service to the nation as a whole. Dr. Benjamin Rush was not a specialist in the modern sense. He could not be. There were not any specialists in the modern sense, as you pointed out. There was no possibility of there being such. But I would like, in this age of specialization, to say one word in the way of a short sermon to eminent specialists. To-day no specialist in a democratic country like ours can afford to be so exclusively a specialist as to forget that one part of his duty is his duty to the general public and to the State. Where government is the duty of all, it of course means that it is the duty of each, and the minute that the average man gets to thinking that government is the duty of somebody else, that minute the republic will begin to go down. It is a fortunate thing for our country that we should have before us the lives of men like Rush, who could take a part in our public life as distinguished as is implied by his having been a signer of the Declaration of Independence, and yet to do it without a particle of neglect of the man's own proper duties."

OBITUARY.

Dr. V. H. Moore died at his home in Brockville, Ont., on June 8, at the age of fifty-six years. He had been in failing health for the past few years, but recently had sufficiently recovered to resume his practice. He was stricken suddenly with heart failure. The late Dr. Moore was graduated from Queen's College, Kingston, in 1870, and practised continuously from that time in Brockville. He devoted much of his time and energy to Queen's, of which he was a stanch advocate and champion. In 1889 he became vice-president of the College of Physicians and Surgeons of Ontario, and president in 1890. He was also made a Fellow of the Royal College of Physicians and Surgeons of Kingston in 1890. He was made an LL.D. of Queen's in 1903, and was a past president of the Canadian Medical Association.

Dr. Rollo Campbell, of Montreal, a prominent young practitioner of that city, and a son of Dr. F. W. Campbell, dean of the medical faculty of Bishop's College University, died last week in that city of typhoid fever. Deceased was about forty years of age and was graduated from Bishop's College in 1886 with honors, and later studied in Edinburgh. From the time of his graduation Dr. Campbell was connected with the teaching staff of his alma mater, and for many years was on the consulting staff of the Montreal Dispensary. He was also one of the assistant surgeons of the Western Hospital, and surgeon of the Fifth Royal Scots.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, held at Atlantic City, N. J., June 7 to 10, 1904.

SECTION ON MEDICINE.

Second Day—June 8th (*Continued*).

(Continued from Page 1143.)

Arteriosclerosis and Angina Pectoris.—Dr. William Osler said that though arteries are usually not associated with painful conditions there are a number of arterial lesions that give rise to severe pain. Edward Jenner, the discoverer afterward of the value of vaccination, was the first to find at autopsy the arteriosclerotic changes of the coronary arteries that are so commonly associated with angina pectoris. Dr. Osler says associated with advisedly, for there are cases of bad degeneration of the heart arteries and their symptoms of arteriosclerosis without any symptom of angina, and on the other hand a certain number of cases of true angina with fatal issue without any changes in the coronary arteries. Changes in various arteries of the abdominal cavity may give rise to attacks of paroxysmal pain resembling angina. On the other hand it must not be forgotten that true angina with lesions in the heart may give rise to pain in the abdomen deserving the name angina abdominis.

Other Arterial Pains.—In migraine there is often an arterial element perhaps consecutive to the attacks but with degenerative associations. The numbness and tingling associated with arteriosclerosis in those of advancing years may give rise eventually to the painful forms of Weir Mitchell's disease. There is a painful conditions of the legs which merits the name of angina cruris rather than that of intermittent claudication which has been given to it. It is associated with degenerative changes of arteries. In old people with arterial changes there is apt to be discomfort in the legs and these same phenomena accompany Bright's disease after arterial changes have occurred and also are seen in diabetes.

Syphilitic Angina.—Dr. Osler considers that there is a definite group of cases of angina dependent on changes in the arteries in and near the heart associated with syphilitic changes. The lesions are noted charac-

teristically at the root of the aorta and at the openings of the coronary arteries. The condition is found usually in young men under thirty-five years, with a clear history of syphilis. The therapeutic outlook in these cases is so hopeful that Dr. Osler thinks they should be emphasized lest any of them should be missed, for a mistake in diagnosis might mean loss of life.

Treatment of Arteriosclerosis.—Dr. J. M. Anders, of Philadelphia, said that the treatment of arterial degeneration must be first of all preventive. Where hereditary elements are at work prophylaxis should begin very early in life. In general there must be avoidance of all excesses. Alcohol in quantities and excessive consumption of nitrogenous foods are fruitful sources of arteriosclerosis. Besides excess of manual labor must be avoided, for it is very generally accepted now that overwork, especially physical exertion to the limit of strength and endurance, is one of the most potent factors in the degeneration of arteries. Dr. Anders considers that the present tendency to overdo athletics at colleges and universities is almost sure to impair seriously the health of the rising generation, and this impairment will be brought about mainly through the arteries. The medical profession of this country should consider it a precious duty to warn young men and those to whose charge they are committed of the serious dangers impending in this matter. Once degeneration of arteries has begun it is indeed difficult to prevent its progress, but absolute prophylaxis is possible.

Physical Therapy.—Even after arteriosclerosis has begun certain things can be accomplished for its relief. The sluggish circulation may be stimulated by warm baths and by gentle massage. For many, part of the difficulty which favored the development of arteriosclerosis is due to the fact that toxic substances in the blood are not properly diluted by a sufficiency of fluid. All arteriosclerotic patients in early stages should be advised to drink plentifully of water—a habit which it will very often be found they have never had. Where the sclerotic changes are more advanced, however, the movement of large quantities of fluid in the circulation becomes quite difficult and then this advice as to free consumption of fluids must be given with more circumspection.

Etiology of Arteriosclerosis.—Dr. Alfred Stengel, of Philadelphia, in opening the discussion, said that the cause of the condition is not single nor the combination of causal elements yet understood well. Alcohol and overwork are important, though the basis of the pathological changes may originate in one of the infectious diseases such as typhoid fever. Years ago Dr. Stengel was surprised to have Sir Wm. Broadbent say that the convalescence from typhoid fever should be prolonged even to a year or eighteen months. Now he understands better the necessity for this. Dr. Stengel considers that the modern overcultivation of athletics is sure to prove a fruitful source of arterial degeneration in some of the most promising of the rising generation.

Responsibility and Arterial Degeneration.—Dr. Frederick C. Shattuck, of Boston, said that not alcohol alone or overwork alone but a combination of factors produces arteriosclerosis. In Scotland and in Scandinavia much alcohol is consumed, yet these countries are not especially likely to have a number of deaths from arteriosclerosis. There life is taken more quietly. It is the rush and stress, the Sturm und Drang of existence, as the Germans call it, which is so noteworthy in America that causes early degeneration of arteries. Dr. Shattuck believes that a series of autopsies on the captains of industry would show this. It is, however, not responsibility itself that is so serious in these cases but the fact that responsibility is not well borne. It is worry, not work, that kills, and the path of death is in this case failing organic involvement elsewhere through the arteries.

Inseparability of Vessels and Kidneys.—Dr. Kraus, of Memphis, Tenn., said that the beginning process of sclerosis in the arteries is a split in the intima with subsequent formation of connective tissue. This is undoubtedly due to high tension, but it is manifestly impossible to separate the kidneys and the vessels in the process. The retention of excrementitious products seems to favor the increase of blood pressure, while any degeneration of arteries affects also the delicate arteries of the kidney structure. Infectious diseases, malaria and yellow fever, quite as well as some of the others mentioned, serve to begin the process which then progresses with every occasion.

Dr. Stockton, of Buffalo, said that for treatment purposes the diagnosis must be made early. Progress may be arrested even when the disease is far advanced. The nitrites are valuable but must be given frequently; nitroglycerin every hour. The iodides are also valuable remedies.

Mitral and Tricuspid Stenosis.—Dr. Judson Daland and E. L. McDaniel, of Philadelphia, collected 186 cases of associated tricuspid and mitral stenosis and discussed their symptomatology. Most of them seem to occur in hearts overdistended as the result of attempts at compensation after endocarditis and simple mitral disease. The mechanism of the associated lesions is apparently essentially protective.

Pleural Effusion in Heart Disease.—Dr. J. Dutton Steele, of Philadelphia, pointed out that hydrothorax due to cardiac disease occurred more frequently on the right than on the left side. In searching for the reason for this Dr. Steele considers that the causative factor is the pressure exerted upon the vena azygos major not directly but by the pulling of the enlarged heart upon the vena cava. Such painless effusions into the thorax always point to the existence of cardiac disease. The fluid nearly always accumulates rapidly after tapping. It seems better, however, to tap, than to have recourse to drugs for the purpose of securing its removal by other means. Dr. Steele reported a series of cases of hydrothorax, showing the position of the lesion and the course of the case.

Prolonged Delirium in Pericarditis.—Dr. E. M. Green, of Easton, Pa., recalled attention to the fact that pericarditis frequently gives rise to protracted delirium and that this symptom may in the absence of other noteworthy signs sometimes call attention to the possibility of pericarditis being present. Dr. Green reported a case of continuous delirium for five weeks not accompanied by marked fever though there was endocarditis. The patient recovered completely and has remained perfectly well without any untoward sequelæ ever since. Within a few months after recovery he was able to exercise freely at an elevation of 10,000 feet.

Limitations of Digitalis.—Dr. Frank Jones, of Memphis, Tenn., discussed the limitations of digitalis in heart disease. In mitral regurgitation digitalis is the most helpful of drugs whenever symptoms are present. On the other hand, in aortic regurgitation it is likely to do more harm than good. The false principle of giving digitalis whenever there is heart disease with symptoms, Dr. Jones considers, cannot be condemned too much. In mitral insufficiency it is the right heart that suffers and the toning up of the heart muscle as well as the toning up of heart nerves are important indications. On the other hand, when there is passive hyperemia and venous stasis the condition is sure to be benefited by digitalis. In aortic regurgitation, however, the left ventricle, owing to the thickness of its muscle

and its capacity for development, is able to compensate up to the limit of vitality and maintain the compensation for a long time. To further whip this willing muscle into activity is like whipping a willing horse overloaded at the foot of a hill.

Aortic Conditions.—As a rule, in disease of the aortic valves there is accompanying arteriosclerosis with involvement of the coronary arteries. Under these conditions the blood supply to the heart is much weaker than it should be. If digitalis be administered the heart is nevertheless asked to do extra work, though it is already in need of nutrition for the work that it is doing. When compensation fails then the left ventricle goes all to pieces; not one part more than another, but everywhere, as Dr. Holmes' wonderful "one-hoss shay." Dr. Jones considers that there is never any justification for the use of digitalis in aortic regurgitation, no matter what the condition of the heart muscle may be. Not infrequently, however, in aortic regurgitation there develops a condition of sleeplessness with dyspnea with marked anxiety. In these cases there is need of a stimulant and, owing to the association of digitalis with heart disease, there is a temptation to use the drug. Fatal results in such cases from its use, however, are not uncommon. Dr. Jones has found nitrate of strychnine of great service in such cases and the indications are for this substance, which tones up the nervous system through the heart and through the vagus.

Morphine with Digitalis.—Dr. James Tyson, of Philadelphia, said that he agreed with Dr. Jones in the main, though as the proof of the pudding is in the eating so the proof of remedial measures is in their application to a special case. Dr. Tyson finds one exception to the general law with regard to the danger of digitalis in aortic disease when there is loss of compensation and both aortic and mitral valves are leaking. If patients are then put in bed and given small doses of morphine, usually not more than one-eighth grain, to which atropine is added, the resulting quietude will soon be noticed. If now digitalis in small but gradually increasing doses be administered without looking for effects too soon, certainly not before the second or third day, the good effects will be surely noted. It is not easy to know the theory on which digitalis does good in such cases, but of the correctness of the practice there is no doubt.

Combination of Aortic and Mitral Disease.—Dr. Richard Cabot, of Boston, said that theory must count for little in the application of drugs for heart disease, and that experience is everything. Personally he has found that digitalis in mitral disease nearly always does good. In aortic regurgitation it as constantly does harm. This is especially true in old persons whose arteries are degenerate or in advanced forms of aortic disease. In young persons suffering from mitral and aortic disease due to rheumatism or some such infectious process digitalis undoubtedly does good, but not so much good as in primary mitral disease. Other combinations of aortic and mitral disease seem also to be benefited by the use of the drug if its administration is not delayed until too late in the case.

Heart Strong, Compensation Failing.—In certain cases circulation failure becomes manifest notwithstanding the fact that the heart continues to beat strongly. In these cases it is important to take off the brakes. This can be done by relieving the circulation of some of its contents by means of purgation and by free diuresis. This method of treating such circulatory disturbances was very familiar to the older physicians and represents the mechanical solution of a serious problem, but is not often employed by the modern physician, who thinks too much of specific drugs for symptoms.

Importance of Rest.—Dr. De Lancey Rochester, of Buffalo, said that he is quite in accord with Dr. Jones as regards the general principles of the use of digitalis in heart disease and considers that a very important element in the treatment of heart affections is rest. The case mentioned by Dr. Tyson, in which there is decided break in the compensation with a combination of aortic and mitral disease will be helped just as much by rest as by digitalis with rest. Small doses of digitalis are very slow to act and do not accomplish near as much as the absolute rest in bed. Dr. Rochester considers that mitral stenosis is also an indication for the use of digitalis and, indeed, to quite as great an extent as is mitral regurgitation. Digitalis, by lengthening both systole and diastole of the heart, gives a longer time and thus enables the auricle to accomplish its work notwithstanding the obstacle in the way.

Dangers of Digitalis.—Dr. S. C. James, of Kansas City, said that to most physicians the word heart disease means at once the use of digitalis; as a consequence digitalis has probably done more harm than good, though there is no doubt that it is a very valuable drug. It would be much better for physicians and their patients, however, if the word heart disease were always associated with the idea of free movements of the bowels, the use of laxatives instead of digitalis. Dr. James has found compound licorice powder and compound jalap powder of more service than digitalis in advanced cases with severe symptoms.

Dr. E. F. Wells, of Chicago, said that severe cases of heart disease are much more amenable to treatment than is usually thought. Great benefit can be secured for lost compensation. When the patient is found with limbs much swollen, sitting in a chair, unable to sleep lying down, and resting very little in any way, morphine in small doses, sometimes not more than one-sixteenth of a grain being necessary, will secure sleep for the patient for hours. Better than any other remedy in conjunction with this, is a cathartic that will produce watery movements. Dr. Wells prefers elaterin, grain one-eighth to one-tenth every three hours, until six or eight watery stools are secured. If, after this, water is removed from the feet by means of punctures, the patient will be made quite comfortable. Then, after forty-eight to seventy-two hours, digitalis may be given with good results.

Venesection.—Dr. J. Sailer, of Philadelphia, said that in his observation aortic disease is more frequent than mitral disease in the ratio of about three to two. Hence the danger arising from the use of digitalis, if the existence of heart disease is to be considered a sufficient indication for the employment of that drug. Personally he believes in taking off the brakes but does not consider that violent purgatives, or the use of diuretics, is always to be counseled. The old writers counseled venesection in these cases and it is wonderful how much can be accomplished for the relief of a laboring heart in advanced stages of heart disease, by free venesection.

Ergot in Heart Disease.—Dr. A. T. Livingston, of Jamestown, N. Y., said that in advanced cases of heart disease, there is prone to be a relaxation of the unstriped muscular fiber in the walls of the arteries. A large amount of the energy exerted by the heart goes to waste then because of the flabbiness of the arteries. This can be overcome by the use of ergot which contracts and tones the relaxed muscle fiber in the vessels all over the body and thus makes the heart efforts much more effective than they were before. Unfortunately ergot has come to be associated with only one use in medicine and it is very seldom thought of in relation to a laboring heart with lack of compensation.

Degeneration of Arteries.—Dr. E. M. Webster, of Chicago, said that aortic disease is very often a result of

the spread of some infectious process, or perhaps a syphilitic process, from the arteries. In such cases no drug could possibly do more harm than digitalis.

Dr. Coleman, of Iowa, said that digitalis does good in cases of aortic disease not associated with arterial change. When there are degenerative changes in either the vessels or the heart itself then digitalis must not be used, or it will do harm. In simple aortic valvular disease, however, without vascular changes, the drug may be of good service.

Dr. Anders said that daily purgation in heart disease is more important than almost any other detail of treatment.

Pitch of Respiratory Sound.—Dr. Charles E. Quimby, of New York, said that while pitch is the element of sound in respiratory diseases most relied on for diagnostic purposes, the common statements to be found in text-books of physicial diagnosis as to the pitch of the sounds heard in normal and consolidated lungs are erroneous. Dr. Quimby showed that the pitch of normal respiration should be stated as inspiration having a high and expiration a low note. During consolidation, the pitch of inspiration is lowered until inspiration and expiration are of the same pitch. Though it is the custom for practically all teachers of physical diagnosis to talk of the expiration in affected conditions of the bronchi, and especially in consolidation as being higher than inspiration, this is never true. Nor is it true in such conditions as emphysema. The laws of acoustics with regard to the pitch of notes varying according to the length and general size of tubes is in accord with Dr. Quimby's differing statement of the real condition of affairs.

Dr. Richard Cabot, of Boston, in discussing Dr. Quimby's paper, said that personally he has written on the subject of physical diagnosis and having spent much time at music, considers that he is in a position to judge of the pitch of breath sounds. In his teaching and writing he has considered that the ordinary statement is correct. Dr. Cabot calls attention to the fact that the pitch of a violin string may be changed without shortening or lengthening it merely by the greater pressure applied by the bow.

Dr. Quimby, in closing the discussion, said that the example of the violin string is unfortunate, since the laws of acoustics as applied to strings in vibration are very different to the notes of a vibrating column of air within a tube, the pitch of which depends absolutely upon the length of the tubes. He has never found that any one who would take the pitch of the respiratory sounds with a tuning fork would fail to agree with him in his radical difference of opinion from those who ordinarily teach physical diagnosis. Very much has been said with regard to sounds in physical diagnosis that is of no value. Some time ago two important teachers of physical diagnosis in New York were teaching within a short distance of each other, that the pitch of the percussion note in emphysema was higher than normal, the other that it was lower than normal. Fortunately for professional dignity and student faith both of them were correct and each of them was wrong.

THIRD DAY—JUNE 9TH.

SYMPOSIUM ON GALL-BLADDER DISEASE.

Etiology of Cholelithiasis.—Dr. Walter L. Bierring, of Iowa City, Iowa, said that the origin of stones in the gall-bladder can be traced in practically all cases to some preceding infectious disease. It might seem as though the gall-bladder by its position was protected from the invasion of bacteria from the digestive tract and that the qualities of the bile itself would further aid in its protection. As a matter of fact, however, the entrance of infectious material is very common. In over 50 cent. of the fatal cases of typhoid fever, in which this point has been carefully investigated, these bacilli have been found in the gall-bladder. On the other hand, traces of the bacteria are constantly found in gall-stones and practically always they form around bacterial products as a nidus. It is not the mechanical precipitation of salts from the bile that used to be thought of, but a true microbic process. Ordinarily the presence of gall-stones leads first to a prevention of contraction on the part of the gall-bladder and thus prevents the proper drainage of the viscus. As a consequence there is an increase of opportunities for infection and cholecystitis is not uncommon when gall-stones are present. By some it is considered that the activity of gall-stones is practically always preceded by cholecystitis and that this is the beginning of the discomfort. As a matter of fact, however, gall-stones may remain undisturbed during a long life and be found only at autopsy. This is true both for large single stones and for many smaller ones, so that it is evident that some other causative agent must be present to arouse stones into activity. The same thing is true with regard to the general etiology of gall-stones.

Contributing Causes.—One of the most important contributing causes has something to do with the sex of patients, since gall-stones are much more common in women than in men. The proportion is three to one or five to one according to various observers. Indeed, gall-stones are like floating kidney, a special attribute of the sex. There are certain good reasons for this. The wearing of the corset constricts the liver and interferes with the circulation of bile, thus preventing proper drainage of the biliary system and facilitating the occurrence of bacterial concretions. Child-bearing, sedentary habits and constipation disturb abdominal circulation and intra-abdominal pressure in various ways, so as to produce like effects. After sex an important predisposing quality is obesity. It occurs particularly in connection with habits of free eating and it is often complicated by nephritis, which is, indeed, the common cause of fatality in operations on the biliary tract. As the result of the over-eating of fat, bile salts become rich in certain salts that may be precipitated and lead to the formation of stones. For a time olive oil was considered advantageous in the treatment of gall-stones, but it has been shown that when dogs are fed on fat almost exclusively small concretions occur in the gall-bladder without infection being demonstrable and no bacillary products are found in the stones themselves. As a rule, some disturbance of digestion seems to be associated with the formation of gall-stones, and this should prove an important hint for the prophylaxis of this pathological condition.

The Gall-bladder, Stomach and Intestines.—Dr. Bertram W. Sippy, of Chicago, discussed the relation of diseases of the gall-bladder and bile ducts to disorders of the stomach and intestines. As the bile passages are situated so near the stomach and upper part of the intestines confusion of symptoms is not unusual. Gall-stones may simulate cramp of the intestines and may bring about vomiting and nausea or even bloody vomiting with a suggestion of ulcer of the stomach or may suggest stenosis of the pylorus. It may even bring about reflex dilatation of the stomach with delay in the progress of food and consequent tetany. The reflex action of the irritation of gall-stones may be seen very well in the epigastric distention noticed after an attack of gall-stone colic which is due to paresis of the muscle of the intestinal walls. This may go even to the extent of paretic ileus on a reflex basis. On the other hand, reflex cramp in the pylorus may be set up simulating a stenosis of this portion of the intestinal tract.

Stomach Symptoms.—The acidity of the gastric secretions has been said to be increased as the result of the irritation of the presence of gall-stones. This would add another element of confusion as regards the differential diagnosis of ulcer of the stomach, since both diseases present pain and tenderness. This hyperacidity, however, has not been seen in a sufficient number of cases to be considered absolute; lactic acid is said sometimes to be present, but unless, where there has been some dilation or motor insufficiency in the stomach, this must be a surprise. Certain pathological conditions in connection with the bile tract are important. Adhesions to neighboring structures, which, of course, will nearly always involve the stomach in some way, are said to occur even after simple cholangitis. When gall-stones are present adhesions are very frequent and are said to occur in 75 per cent. of all cases. The gastralgic pains which are so often said to be due to adhesions in these cases are not necessarily so, and may be relieved by operation. Bands of obstruction which are sometimes found at operations upon the stomach and intestines, can nearly always be traced to a severe cholecystitis, the history of which will be found some years before.

Simulation of Stomach Disease.—Affections of the biliary tract may simulate tumor of the stomach and be considered to be cancer of that organ. As the result of the conditions which developed in connection with gall-stone disease, benign stenosis of the stomach may occur and patients be allowed to die under the false impression of malignant disease, though they are really suffering from a relievable condition. Fistulæ of the gall-bladder and ducts may occur in connection with nearly every part of the intestinal tract and are much more frequent than used to be thought. Occasionally, affections of the stomach in association with a gall-bladder disease are quite tractable, even by medical means. When the contraction of the pylorus is reflex, patients may be put to bed and by means of rectal feeding complete rest given to the upper part of the digestive tract. After a time it will be found that small quantities of milk can be taken and that the motor sufficiency of the stomach is resumed, even in cases where sarcinæ have been present. Gradually the amount of food taken may be increased and so the irritative contraction of the pylorus overcome. At times, too, when the stones are removed from the biliary passages the plastic exudate thrown out around them may be reabsorbed. The outlook then is not always as alarming as has been thought.

Gall-stones and the Intestines.—Occasionally, surprising as it may seem, gall-stones occlude the intestinal lumen and cause symptoms of obstruction. Fifty per cent. of these cases perish. On the other hand, ileus may be set up, not entirely because of the size of the stones, but because of the irritation it produces. One stone, 9 by 13 cm., passed to the anal region before it was stopped. Usually the place of stoppage is at the ileocecal junction where the lumen of the intestine is smallest. The ileus which occurs is due to the paresis of the intestinal walls as the result of irritation. Very large stones ulcerate their way from the gall-bladder into the intestines and the process is so slow that there may be no history of the passage of gall-stones. In gall-stone ileus there is usually less shock and prostration than in other forms of intestinal obstruction, and while there is fecal vomiting there is usually also a number of passages from the rectum. As to the differential diagnosis of ulcer of the stomach and duodenum and cholelithiasis, it is prone to be very difficult. Icterus is sometimes said to be a pathognomonic sign of gall-stones, but in reality is relatively rare, occurring, according to Riegel, only in 10 per cent. of the cases of gall-stones. Vomiting of blood, on the other hand is not pathognomonic of ulcer, for it does not occur in all ulcers, and has been noticed in gall-stones without any stomach lesion. Examination of the stomach contents may be of assistance. If the secretions are normal and the motility good after a testmeal, it speaks against any affection of the stomach and points to gall-stone disease. All symptoms of these cases, however, must be studied in order to make the differential diagnosis of these affections.

Surgical Diagnosis of Gall-bladder Disease.—Dr. Parker Syms, of New York, said that one out of every ten persons has gall-stones. In only about five per cent. of those who have them, however, are there any symptoms. Most of those who have any symptoms present classical types of the disease. Some patients, however, have anomalous symptoms and the true significance of their affection is missed. As Dr. Lambert, of New York says, the gall-bladder represents a mysterious realm of surgical romance in the right upper quadrant of the abdomen. The most characteristic symptom of gall-stone, is pain which may be relieved by eating, which occurs most often when the stomach is empty and the relief of which is usually followed by the passage of gas from the intestine. The character of the pain is rather typical. Patients describe it as a boring through the abdomen to the vertebræ. The maximum of pain is felt just below the free border of the ribs. The point of greatest tenderness, as pointed out by Mayo Robson, occurs on a line from the ninth rib of the umbilicus, and is definitely located here, even when for some reason there is displacement of the gall-bladder because the tenderness is really due to nervous reflexes. According to Kehr and others, pain is due to the inflammatory condition of the gall-bladder. According to Murphy, it is due to the irritation of the stone itself. Subsidence of pain is usually welcomed as the end of an attack. As in appendicitis, however, it may be due to gangrene, or perforation of the stone through the bile tract, with serious results. At one time it was thought that the X-rays would prove a valuable diagnostic aid in the recognition of gall-stones. This agent has proved unsatisfactory, however; whenever the X-ray verdict is positive it settles the question; negative X-ray evidence, however, is not conclusive.

Differential Diagnosis of Gastric Ulcer.—Owing to the fact that gall-stones may produce acute indigestion, they may simulate gastric ulcer very completely. Usually, however, the point of maximum tenderness in gastric ulcer is higher up and is in the median line in connection with ulcer. The chill and fever common in gall-stones are absent in ulcer. The pain of ulcer occurs after the taking of food, while gall-stone colic occurs at night when the stomach is empty. The absence of tenderness at Mayo Robson's point is of value.

Differential Diagnosis of Appendicitis.—When the appendix is displaced it may be necessary to diagnosticate between affections of this order and the gall-bladder. There is a difference in the character of the pain, which is not so boring in appendicitis and which does not radiate toward the shoulder as does gall-stone colic. There is besides in appendicitis an extreme rigidity of the right rectus muscle. Reflex vomiting is more common in appendicitis and there is an absence of any tendency to jaundice. Where the condition is not fulminant a wait of twenty-four hours will usually determine the question, since the gall-stone patient will usually be much better at the end of that time than the sufferer from appendicitis.

Other Painful Abdominal Conditions.—The differential diagnosis of stone in the kidney may be made

by the different character of the pain, its different radiation and the absence of tenderness at the Mayo Robson point. Pancreatic colic causes pain in the median line or on the other side of the abdomen and usually with the presence of fat in the stools. Phlebitis portalis, that is, inflammation of the portal vein, may occur after neglected appendicitis and is diagnosed by the history of the patient and by the existence of a septic temperature.

Local malignant disease of the stomach may be differentiated by careful examination, but often an exploratory incision will be necessary. Empyema and subphrenic abscess are sources of confusion in diagnosis, but usually the general condition of the patient, the temperature curve and the extension of dulness upward in the liver region are sufficient to make the differentiation. It must not be forgotten that in certain cases of angina pectoris there may be acute abdominal pain, referred to the region above the umbilicus rather than to any part of the thorax. In these cases an examination of the heart will usually disclose the existence of a serious heart condition with which the pain is associated.

Surgery of Gall-stones.—Dr. Lucius W. Hotchkiss, of New York, said that while much has been attempted in the matter of dissolving gall-stones by various means, little if anything has been accomplished. It has been found that when the gall-bladder is healthy, as in dogs, gall-stones placed therein are gradually dissolved. Once the gall-bladder has become infected, however, stones are not dissolved. It has been thought the use of bile might prove of service in aiding the gall-bladder to dissolve stones and to some extent good has been accomplished in this way. It is, however, of very limited application: at one time was considered to be of great service but has not fulfilled the hopes of those who used it and indeed seems to have a tendency to increase the amount of bile salts and thus lead to the deposition of material in the gall-bladder. The Carlsbad cure still does good, and it is evident that a plentiful supply of water with a certain amount of laxative action is the best medical therapeutic measure there is for gall-stones. At the present time, the treatment of gall-stone disease lies between this form of hydrotherapy and surgery. It is encouraging to find that at the present time there is much less tendency to the production of the opium habit and much more recourse to active surgical measures.

Early Diagnosis.—The future of the proper treatment of gall-stones lies in prompt diagnosis rather than in an improvement of the technical operation. Where cases are uncomplicated, the mortality of operation at the present time is low and is mainly accidental. Danger lies in delay in recourse to surgery, since complications develop. Where there is only one small stone there may be a very slight tendency to disturbance and this may be relieved by the passage of the stone. Even where there have been several attacks with stones passed at each one but at long intervals, surgeons are inclined to wait. Where, however, attacks are recurring at shorter and shorter intervals, then the ideal operation is cholecystectomy early in the case and the mortality of such operations is not high. Lilienthal has done 37 such operations, with only one death and that for another reason than the operation itself. It is evident then that surgery must be the recourse of those who would wish to treat this serious condition rationally and that the decision to permit surgical intervention early is almost sure to prove not only life-saving, in many cases, but also saving of complications and serious sequelæ.

(To be Continued.)

SECTION ON SURGERY AND ANATOMY.

SECOND DAY—JUNE 8TH.

(Continued from Page 1148.)

Factors in the Mortality of Appendicitis.—Dr. F. LeMoyne Hupp, of Wheeling, W. Va., in the discussion, said that one of the factors determining a fatal issue, where there has been a beginning diffuse septic peritonitis antedating the surgical interference, is a continuance of this process. Of the seven cases of this kind that have come under his care in recent years, and receiving operation, two have died in this way. Practically all other deaths in these cases are a result of well-known and recognized causes. Within the past four weeks there had come under his care a patient with appendicitis, who presented an unusual feature in his experience in these mortality factors. A boy, fourteen years of age, was admitted to his service in the City Hospital of Wheeling, W. Va., who had been treated by his family physician for typhoid fever for a period of eleven days prior to admission. His symptoms seem to have been typical up to the tenth day, when there was discovered an induration and localized tenderness in the right iliac region. On the day of admission (May 6), under chloroform narcosis, the usual incision was made and about an ounce of very offensive pus was removed from the retrocecal region. In the washing there escaped a tubular segment of the appendix vermiformis, much resembling a macerated piece of macaroni. A suspiciously dark area was detected over the cecum. Because of the profoundly collapsed condition of the patient no further interference was deemed advisable. Well-directed drainage was established and the patient removed from the table. Forty-eight hours after the operation the dressing was saturated with a dark, offensive, coffee-grounds fluid, and at times there seemed to be some fresh-looking blood with the exudate. The drainage strips were removed and there welled from the depths of the wound a quantity of decomposed, black blood clots. Collapse and death followed three days after the operation. The real interest in this case centered in the autopsy. No remnant of the appendix was discernible. A very extensive extravasation of old decomposed blood was found distending the cecum, ascending colon and part of the ileum. Peyer's patches exhibited the typical typhoid lesion and an eroded vessel in the base of one of these ulcers demonstrated the seat of the hemorrhage and the cause of death.

THIRD DAY—JUNE 9TH.

The Anatomy of Inguinal Hernia.—Dr. D. N. Eisendrath, of Chicago, presented two very large and perfect models illustrative of the anatomy of the inguinal region. He said that he had found these of great use in his teaching work and stated that sweater cloth of different colors was the best material for the purpose. He stated that the weak regions in the inguen depended on two factors, viz., (1) upon the degree of arch of the deeper muscles; and (2) upon the size and strength of the inner oblique. He gave an interesting and detailed description of the history of the operation for hernia and illustrated his method of teaching with the models.

Andrews' Technic.—The sum and substance of Andrews' operation is that he sews the external oblique, the internal oblique and the transversalis to Poupart's ligament behind the cord. He then places an imbrication stitch, which creates a fold of the aponeurosis of the external oblique about the cord; this latter structure, in other words, lies in the position usually occupied by it after the application of the Halsted technic, except that it is protected from injury, as it is not by

the Halsted method, by being folded under the tissue of the external oblique. The reader said that he believed that this operation gave greater strength to the weak parts without in any way sacrificing the cord, than any other known method.

Three Years' Experience with the Autoplastic Suture for Hernia.—Dr. L. L. McArthur, of Chicago, before stating the results of his 93 cases, passed around a most beautiful specimen which showed his method of separating the living ligatures from the fibers of the external oblique. As is well known, he bluntly dissects off two substantial threads from each side of the wound, which is made in a direction absolutely parallel to the fibers of the muscle. One of these is then used for the deep suture, the other for the superficial. The patients furnishing this series of 93 cases average in age from seventy-eight years to six months. The ingenious author stated in defense of the use of the living ligature that he had had an opportunity of examining the ligature after it had been *in situ* for six months in a patient who had aptly died of some extraneous disease. So far as could be observed from the histological condition of the tissue, the fibrous thread was as thoroughly alive as when it was separated from the external oblique. Furthermore, he stated that in the event of suppuration taking place, the condition would be no different from that which obtains if catgut ligature had been used. The fibrous autoplastic suture would simply die and be absorbed.

Dr. William B. Coley stated that the need for Dr. McArthur's technic had in a measure passed by. If it had come to the notice of the profession (which unfortunately it did not) ten years ago, when sterilization of absorbable materials was not so far advanced, it would have been a more invaluable addition to surgery than it at present constitutes. He believed that the kangaroo tendon prepared by modern methods could be made as sterile as the autoplastic suture, and there was this in favor of it, that it was not prepared during the time of operation.

Dr. E. W. Andrews, of Chicago, said that his method of doubling the external oblique over the cord was merely the application of an old and well-known technic to this particular operation. The principle had been employed by Mayo in his well-known operation for the relief of ventral hernia, and he believed that, while the ordinary Bassini might give equally satisfactory results in the average run of cases, still there were undoubtedly a large number of patients whose belly walls were extremely deficient. In this type of patients, the imbrication stitch allowed the triple protection of the weak area by affording a guard to the cord.

The Autoplastic Sutures Live.—It had been his privilege to see the sections reported by Dr. McArthur, and in his opinion they were very much alive at the time of the patient's death. He believed that the utilization of the living sutures had a great future, not alone in hernia, but in many other operations as well. There seemed no reasonable doubt that the living cord woven between two tissues could hold them together better than one which stayed in the parts only until union took place and was then absorbed.

Dr. Bloodgood, of Baltimore, complimented Dr. Andrews very cordially upon his imbrication method. He said that Dr. McArthur was a sort of peace commissioner in the matter of herniotomy, because he employed no definitely fixed operation, but utilized any technic for his autoplastic suture. He said that of course time was the essential test of the merits of a herniotomy technic. Transplantation of the cord was no longer practised at the Johns Hopkins Hospital. In his opinion, the satisfactory and efficient suture of the internal oblique muscle to Poupart's ligament, aside from suppuration, was the most important element in success. He believed that Andrews' method probably gave better results than any other known technic. In closing he advised the resection of a certain proportion of the veins of the spermatic cord, which in his opinion greatly favored the permanency of the operation.

Dr. Marcy, of Boston, said that his old teacher, Oliver Wendell Holmes' favorite aphorism on the anatomy of the inguinal canal was that it resembled kindling wood, "the more sticks you split, the more you may." Marcy began to advocate and to do hernia operations thirty-four years ago and from that early date to the present he had been advocating buried absorbable sutures.

Dr. Arthur D. Bevan, of Chicago, described the technic which he has gradually evolved and which he used on the majority of his cases. He said that Andrews' operation was undoubtedly of inestimable value under certain circumstances. He urged that great care should be taken not to injure the tissues any more than could possibly be helped, and to this end he advised that only the portion of the sac which lay directly in the inguinal canal should be excised, such of it as passed into the scrotum doing no harm whatever if left there. In 25 per cent. of his cases, he has employed infiltration anesthesia. In closing he urged that the sutures must all be absorbable.

Surgery of the Trifacial Nerve and Its Ganglia.—Dr. John B. Murphy, of Chicago, divided the subject into five stages: (1) Resections of branches down to the cranial foramina; (2) Division of branches within the cranium, with efforts to occlude the foramina; (3) Removal of the Gasserian ganglion, with intracranial segments of nerve; (4) Extraction of sensory root; (5) Intraneural injections. He said that although he was loath to admit it, he had been forced to the conclusion that the intracranial operation was too menacing to life to allow of its indiscriminate employment if any other technic can be devised to take its place. Of pathology, the author admitted, practically nothing is known, which, however, makes little difference to the patient. What he wishes is to obtain relief from the excruciating pain. He stated that in his opinion regeneration of the nerve after section of its root might be absolute. If such regeneration, he said, were the basis of the return of pain, some operation should be perfected to prevent it. He believed that the ganglia, which are located along the course of the nerve, particularly otic ganglion, played a very important part in pain production. He cited 11 cases in which he had employed osmic acid injections. He detailed their histories in full. This injection, he said, was practised twenty years ago, but the mistake had then been made of introducing it into the tissues and not of necessity into the body of the nerve itself. This is of absolute importance, for if the injection simply passes beneath the sheath of Schwann, no results can be obtained.

Effect of Osmic Acid Injections.—The patient first notices the diminution of pain. This gradually increases until at the end of about three days, anesthesia is complete. He admitted that the permanency of the cures which he reported was not yet assured, but stated it to be his belief that the osmic acid treatment, if properly used, would give a great deal of relief to suffering humanity.

Intracranial Neurectomy for Trigeminal Neuralgia.—Dr. Harry M. Sherman, of San Francisco, reported five operations in four patients. In three of these there was absolute recovery from pain, but one suffered the unfortunate complication of seventh nerve paralysis. In

the last two operations, which had been practised on the same patient, the root of the nerve was cut behind the ganglion. That it was certainly cut was attested to by the fact that there was motor disturbance of a very pronounced character at the moment of section, and further by the fact that section was followed by complete paralysis of the pterygoids. He stated that the technic of Frazier had been carried out, but that it had evidently failed because of the union of the nerve immediately after section. He advocated filling the wound area with normal salt solution just prior to closure, because he believed that this prevented an extensive hemorrhage and was subsequently absorbed. This would naturally limit the formation of scar tissue which develops largely from clots.

Division of the Sensory Root for Tic Douloureux.—Dr. Charles H. Frazier, of Philadelphia, said that he believed his researches had at length demonstrated without doubt the value and success of the technic of resecting the sensory root. He recommended that in those cases where the root could not easily be distinguished, a resection of the posterior portion of the Gasserian ganglion be made. This, in his opinion, would produce the same results as resection of the century root. He considered that the question of regeneration of the root after section was a closed one, because, in his opinion, it was impossible for this to take place. The results of his operations were not capable of positive interpretation as yet, however, because the time in the oldest one was twelve years and eight months, that of the most recent being fourteen months.

Dr. Spiller, of Philadelphia, said that he had invariably found marked degeneration in every part of the nerve and these ganglia when he had studied specimens removed from marked cases of tic douloureux. Inasmuch as there is this general degeneration, it seems self-evident that central is preferable to peripheral section. He advised that a portion of the root should be removed, not to guard against possible reconstruction of the same, but to insure its entire section.

Dr. Robert F. Weir, of New York, said that he had employed osmic acid twenty years ago and was very sorry to say that in his hands it had never proved at all efficacious. Perhaps the secret for this lay in the fact that he had not properly and thoroughly injected it; but he feared that the conviction, which had been forced upon him some years since, that for the relief of a serious facial neuralgia the final court of appeals must be an intracranial operation, was correct. So far as the possibility of nerve regeneration in the case of the posterior root went, he believed that it was quite possible for this phenomenon to take place. In commenting upon Abbe's method of placing gutta percha tissue between the cut segments to prevent their growing together, he recalled two cases in which he had allowed gutta percha tissue to remain in the brain. Each one of these pieces was perforated by newly formed filaments.

Dr. Horsely, of Richmond, said that in his opinion the personal factor was a very important one in determining the regeneration of nerves. He advised the employment of Cushing's technic and suggested that it should be furthered by carotid ligation. He admitted the advantages, particularly those obtained in the eye, which accrued from sensory root severance, but stated that in his opinion complete avulsion of the ganglion would be necessary in a certain number of cases.

Dr. J. H. Cushing, of Baltimore, said that for cases of the genuine facial neuralgia, there was an indirect mortality due to suicide of just about 50 per cent. For this reason, if for no other, a capital operation, which was attended by as low a mortality as the modern intracranial method had recently been shown to have, was not only justifiable, but in his opinion obligatory. This statement, he wished it distinctly understood, applied only to the profound cases of nerve involvement, through the constant pain of which the patient's life is rendered miserable. In the last 16 cases he has lost but one, the horizontal method of reaching the ganglion having reduced the mortality to five per cent.

Dr. John B. Murphy said that he believed he could recognize the real thing and that his injections had been done on genuine cases of facial neuralgia. He said that but little was at present known of the cause of interruption of nerve function. Why, for instance, should section sometimes fail, while paralysis from pressure of short duration may be permanent?

Dr. Sherman, in closing, said that there was no question in his mind that he had succeeded in severing the root of the nerve, for the reasons given. Until he had positive proof to the contrary he should continue to believe that regeneration of the posterior root after simple section as advised by Frazier is not alone possible but probable.

Laminectomy.—Dr. John C. Munro, of Boston, made an earnest plea for simplification and perfection of the technic of laminectomy. He said that most of the laminectomies which the surgeon would be called upon to perform were associated with fracture dislocations. Lloyd's dictum that patients showing evidence of a double transverse lesion should be left alone, he deemed as faulty, obsolete and most dangerous. This position was readily explained by the fact that no man can be positive in his interpretation of symptoms until the time of operation. He spoke of the pathology of suppression of function in nerves, stating that we know enough to be certain that it was not a mere degeneration. He advised operating even in chronic cases for the reason that in two such he had had most gratifying results. Truly these were the product of a long series of discouraging failures, but they were enough to justify the possibility.

Dr. Lund, of Boston, in opening the discussion of this paper, said that much of the success which was to be hoped for in the future of these operations could be attributed to the painstaking and continuous efforts of Dr. Munro to perfect the technic and to improve the impliments used in laminectomy. He said the discouraging nature of the work was well calculated to turn the activities of investigators and operators into other channels. He emphasized the danger of attempting to make a positive diagnosis from symptoms alone.

Dr. Cushing said that hematomyelia was practically unrecognizable from bone pressure occurring in the spinal cord.

The Treatment of Cold Abscesses and Sinuses in Tuberculous Disease of Bone.—Dr. V. P. Gibney, of New York, first detailed the effects of modern life and environment on the development of this class of lesions. He said that in the opinion of many orthopedic surgeons, the ground was still held that it was wise under any conditions to allow of no interference, but to hope that under protection and extension they would absorb. That in a great many cases this takes place cannot be doubted. But the fact remains that this treatment is by no means ideal. He then drew attention to the existence of the opposite class of operators who treat these abscesses on the principle that pus should be evacuated wherever found. A middle ground was to be distinguished as represented by the class of surgeons who advise aspiration of these cavities with or without the injection of antiseptics. Experience of a great many years had taught him that the best results were to be obtained by early recognition of the abscess, its immediate opening and,

in the event of the pus being sterile, its complete closure. Its technic is, however, hardly ever available. If on aspiration there is found to be a mixed infection, drainage might much better be established by the surgeon than by nature. This mixed infection is a most direful calamity.

Old Unreduced Dislocations.—Dr. DeForest Willard, of Philadelphia, said that old chronic dislocations demand much greater gentleness of treatment than the recent fall. The time would come, he hoped, when one should be able to say that the treatment of this condition had ceased to be of importance, because the lesion itself had ceased to exist. He described Allis' work in considerable detail, and concluded that in operating upon dislocations, it was essential to cut all the soft parts, which in any way interfered with the proper reduction. He would also advise an avoidance of operation in cases upon whom a number of previous operations had been made on the same site, because of the increased danger from depressions of the tissues of sepsis.

Dr. Arthur D. Bevan, of Chicago, commented on the very great value of the X-rays in diagnosing dislocations. In injuries of the more inaccessible joints, they rendered less to be dreaded the frequent complication of fracture. In operating upon the elbow, he advised the careful saving of the triceps tendon. In old chronic dislocations of the elbow, he had found the best results to arise from a resection of the head of the bone.

Dr. Joseph A. Blake, of New York, also commented favorably upon the value of the X-ray. He said that, except in very rare cases, mechanical methods of reduction were valueless and dangerous. For the shoulder, he advised the open incision, which should be placed as far forward as possible to avoid the tissue of the deltoid. He utilizes a lateral incision in the elbow-joints and stated that it had been his experience that the results of operative intervention in this region were far better than those obtained at the shoulder. This he accounted for by the fact that the shoulder girdle was freely movable. This interfered with the application of any considerable degree of force in passive movements.

Conservative Perineal Prostatectomy.—Dr. H. H. Young, of Baltimore, cited the history of the development of the operative work on the prostate as it had occurred in his hands at the Johns Hopkins Hospital. First he had done the suprapubic operation, then discouraged with this, he had turned to the Bottini technic, and finally he had become convinced that the operation of choice was perineal prostatectomy. In his series of fifty cases, he had had no deaths. He described the technic of his operation and illustrated his remarks with a beautiful series of diagrams. He considered a transverse incision through the skin to be essential. Further he believed that every effort should be made to save ejaculatory ducts and the urethra.

Prostatic Obstruction.—Dr. Parker Syms, of New York, said that the modern methods of diagnosis were, or should be exceedingly simple, except under extraordinary conditions in which the cystoscope should be employed. He reiterated his well known points of objection to the suprapubic route and to the Bottini, believing that both would soon fall into well deserved oblivion. So far as catheter life was concerned, he expressed his belief that the period of its enjoyment, which has been stated to be four years, was altogether too high. It should probably be divided by two or a greater number. He utilizes a simple median incision, opens the urethra, passes in his well known double retractor into the bladder and shells the prostate out. There is practically no hemorrhage, and the length of time needed for the technic is about seven minutes. He stated that he had recently come to the conclusion that there was no sense in keeping these patients in bed, inasmuch as the operation might justly be considered one belonging to minor surgery. He therefore allows his patients to get up in from twenty-four to forty-eight hours. In his last 34 cases he has had two deaths.

Prostatectomy by the Perineal Route.—Dr. George Goodfellow, of San Francisco, spoke of the horrors of catheter life. He said that no instrumentation of the bladder should be practised if it could be avoided. His operation is practically identical with that of Syms with one exception, that he uses no retractor. The question of the pathology of the middle lobe was still moot. Physiologically this is probably absent, but pathologically it is present in most cases and usually springs from the commissure. In giving his technic, he agreed with Syms and previous speakers that it should be as simple as possible; no bladder washing, and as little dissection of the perineum as possible. He utilizes a low, old-fashioned lithotomy staff that has an extensive curve quite different from the modern, straight instrument. The position of the patient is of the utmost importance, the knees being flexed so as to reach into the armpits. Sixty-seven years was the average age of his patients, and in 78 operations he has had but two deaths.

Is It Wise to Try to Make Any One Operative Method Apply to All Prostatectomies?—Dr. Eugene Fuller, of New York, discussed the subject as it was presented to him from the results of 300 operations for removal of the prostate. He cited the indications for and against the suprapubic and the perineal operation.

Dr. Martin B. Tinker, of Ithaca, spoke of the great importance of using massive infiltration anesthesia for these cases. He uses eucaine with adrenalin, one to one hundred thousand. The entire perineum is supplied by the pudic and long pudendal nerve. These course around the inner aspect of the tuberosity of the ischium and in any subject, but particularly in the rather emaciated cases which usually come to operation, one can strike the nerves and infiltrate them without the least trouble. On account of the fact that the morality of the operation is largely caused by general anesthesia and partly too because of the objection which most patients entertain to this, it is very desirable that local anesthesia be employed.

Dr. Syms, in closing, said that the highest tribute which could be possibly paid to the perineal method, was to be found in a simple addition of the cases presented at the meeting and an estimation of their mortality. One hundred and sixty-three cases had been cited and of these four had died, the percentage being thus reduced to the nominal sum of $4^{4}/_{10}$.

Kidney Stone, Diagnosis and Treatment.—Dr. Arthur D. Bevan, of Chicago, mentioned briefly the more important etiological factors and gave statistics as to frequency, sex, age and geographical locality. He regards a mild bacillus coli infection of the kidney as probably the most common cause of stone. The typical picture as presented in text books is rarely followed He cited the conditions from which renal stone has to be differentiated and concluded by emphasizing the importance of the X-ray. Cryoscopic examination of the blood has in his hands proved most valuable in determining the condition of the renal epithelium. The treatment he divided into three groups. First, expectant. This might be employed where symptoms were not severe and should in his opinion be combined with the giving of glycerin internally and the introduction into the ureters of vaselin oil. Calculus anuria of course necessitates immediate operation, and as it is inconceivable that stones should lodge simultaneously in each ureter, it proves that one ureter is not infrequently occluded without giving rise to more than passing

symptoms. There is but a three per cent. mortality in non-suppurating cases. He would not advise the stripping of the capsule. He gave the technic of his method of operation, stating that he used a sweeping incision similar to that advised by König. The kidney should be brought upon the surface before incising it. After that is done, there is no need of considering any lives of diminished vascularity, because the hemorrhage can always be easily controlled. In stone of the pelvis, he advises a free incision of this organ. In conclusion, he wished to emphasize the importance of the X-ray in diagnosis and that early incision and removal should be practised and, in the absence of suppuration or of obstruction of the ureter, should be followed by no drainage.

Dr. C. L. Leonard, of New York, read a statistical review illustrative of the value of the X-ray as a means of diagnosing renal stone.

Dr. Joseph A. Blake spoke of the great value of Dr. Bevan's paper and expressed his wish that it might be more generally known that with suitable apparatus admirable X-ray pictures could be made of these stones in from six to eight seconds. He discussed the frequency with which unilateral calculi of the ureter often remain latent. This, he said, was an additional cause for utilizing the X-ray, because such calculi are extremely dangerous. He then discussed the question of primary or secondary nephrectomy and stated that his experience had led him to the conclusion that the kidney had better be removed at the first operation. He endorsed Dr. Bevan's attitude that in the absence of compromising conditions the wound after nephrotomy should be closed without drainage.

FOURTH DAY—JUNE 10TH.

Dr. A. J. McCosh, of New York, was elected Chairman of the section; Dr. F. W. McRae, of Atlanta, Ga., secretary.

Treatment of Fractures of the Patella by Lateral Suture.—Dr. Joseph A. Blake, of New York, detailed the anatomy and pathology of the involved parts in considerable detail. He drew particular attention to the so-called lateral patella ligaments which are instrumental in fastening the vastus internus and externus directly to the tibia. In fractures by direct violence alone they are not torn, and suffice to keep the fragments in apposition. He said that a knowledge of this anatomical fact is necessary for the establishment of a rational mode of treatment. The indications for operation are determined exclusively by the degree of tearing off the lateral ligaments. These are apt to remain intact in fractures caused by direct violence, whereas they are almost invariably torn when injury results from muscular violence. The latter cases are better treated by operation while the former yield good results by mechanical treatment only. In discussing the technic, he said that there were two points which he wished to emphasize. The first was a general one and was not original with him, although enough attention had not been given to it. It was simply to the effect that a suture of the lateral ligaments alone was quite sufficient. The second, a point which he believed had not been commented on before, the necessity of placing the stitches as close to the bone fragments as possible. This is absolutely essential in securing their coaptation so necessary to bony union. He advised a transverse incision and stated that he always made use of silkworm-gut sutures without drainage. The simplicity, ease and rapidity of this method are self-evident. An important factor not to be overlooked consists in the ability of the operator using it to avoid traumatism of the tissues such as is of necessity inflicted in any bone drilling operation. He advised massage and kindred treatments, fifteen to twenty days after operation, and believed that the time of election for operation was from the forty-eighth hour to the fifth day.

Twenty-two Consecutive Successes.—This had been the record since the adoption of this technic. Two patients had refractured their patellæ, both of whom were reoperated. There was at the second operation no evidence of a fibrous union, and great force had evidently been exerted in causing the fractures.

Dr. Gibbon, of Philadelphia, said that he could simply endorse Dr. Blake's paper, but he wished to add that age up to sixty was not a contraindication, but that alcoholism distinctly was.

Dr. Vaughn, of the Marine Hospital Service, said that although he had been able to obtain free access to the joint by a long longitudinal incision, the transverse section recommended by Blake undoubtedly gave more room. He had recently been using silver wire.

Dr. Binney, of Kansas City, said that the bugbear of bony union in these cases being essential, was at length destroyed. The real meat in the cocoanut lay in deciding first upon early operation, and second upon a thorough suturing of the lateral ligament. They do the work.

Dr. Rodman, of Philadelphia, said that Blake's observations were based on thorough anatomical and surgical principles. He was surprised that the operation which had originated in Great Britain was not so popular there as here. He affirmed that no surgeon should operate on the knee-joint without realizing and confessing to his patients that there was in its execution an element of danger both to limb and to life.

Dr. Eisendrath, of Chicago, said that some sixteen months ago he had hit upon Blake's operation through having to suture the soft parts in default of his bone drill. His technic was identical with Blake's with the single exception that he favored the insertion of two periosteal stitches where this membrane crossed the anterior surface of the patella to prevent its falling into the fracture.

Dr. Bullard said that the nomenclature of the subject should be changed from fractured patella to ruptured ligament. He asked why Dr. Blake operated so early when many other surgeons advised waiting ten or twelve days.

Dr. Charles A. Powers, of Denver, said that eight or nine years ago he had been appointed to report on the matter of operation for fractured patellæ. He had approached the subject as a skeptic, but had soon become converted. He agreed in all details with Dr. Blake.

Dr. Blake, in closing, said that long chromicized gut was worse than silver wire. In answer to Dr. Bullard, he stated that he had formerly waited for a week or ten days, but had come to the conclusion that a good deal of effort at repair had by that time been made. This necessitated the cutting of more tissue than in the case of an earlier operation.

Surgical Treatment in Certain Cases of Arthritis Deformans.—Dr. Martin B. Tinker, of Ithaca, said that before any useful surgical treatment could be devised, careful study must be made of the etiology and pathology of the condition. Of the former we know but little. Many writers have confused it with rheumatism, but there is no question that it is an entity separate and apart from this. Others have ascribed to it a nervous origin. While nervous strain and general bodily fatigue may be factors, still it does not seem possible to believe that they are the only agents. Infection by a specific organism appeals more earnestly to the thoughtful observer. And all surgical treatment should probably be based on the supposition that infec-

tion is responsible for the disease. The pathology is equally important. As is well known, it attacks the larger joints, but may after a period of twenty years or more have invaded almost every joint in the body. Primarily the disease is entirely extra-articular, but sooner or later changes, which give rise to the well-known mushroom deformity, take place in the ends of the bone. In diagnosing the condition, it should be remembered that it occasionally is present in but one large joint and may therefore not unreadily be mistaken for tuberculosis.

Value of Tuberculin.—He had injected 400 patients with tuberculin. Many of these had had arthritis deformans and in not a single instance had he obtained any reaction. As regards the extent of disability, he said there were at the institution at which he was attending surgeon no less than one dozen men and women who had been rendered so utterly helpless as to be unable to rise from their chairs or to be manipulated in any way.

Surgical Treatment.—While the various springs are able to give palliative treatment and this for the time stays the course of the disease, there is no doubt that a certain proportion of them progress until they are justly within the realm of surgical help. The simpler operation of arthrotomy should be practised to the absolute exclusion of brisement forcé, because by the pathology, it is known that there are no adhesions to break up, but that the joint is locked by small osteophytes.

Six per cent. of a series of 200 cases which he had recently seen in consultation were deemed fit subjects for operation, and in them arthrotomy, or in one or two cases arthrectomy, had given almost brilliant results. He believed the latter operation to be indicative in the presence of absolute fixation or for the relief of extreme pain.

Dr. Vaughn agreed with Dr. Tinker that probably arthritis deformans is of infectious origin. He said that the fever, which could always be recognized, if the cases were carefully watched, at their very beginning, suggested this. He had operated on the same woman three times by brisement and had succeeded in getting a very good result.

Dr. Sherman said that the value of the removal of osteophytes and exostoses had in the past been entirely unappreciated. He asked whether any evil consequences might be feared as the result of opening a diseased joint?

Dr. Tinker replied that in the quiescent cases upon which he had operated, he had experienced no more difficulty than is to be looked forward to in a normal joint. He described his method of immobilizing the shoulder at right angles to the trunk and the restitution of function by gradual and continued passive motion.

Impacted Fractures of the Neck of the Femur.—Dr. Lemoyne Wills, of Los Angeles, presented the radiographs of two interesting cases, the histories of which he gave in detail. These radiographs demonstrated very clearly the necessities for radical surgical interference if cure was to be effected.

Fat Embolism of Lung Following Fractures.—Dr. F. G. Connell, of Leadville, Col., stated that this important subject had been thoroughly thrashed out on the continent, but had for some inexplicable reason been treated with neglect both here and in Great Britain. He said that the discovery of fat globules in the sputum or urine of a suspected case would establish the diagnosis. The prognosis is grave. Fat emboli after passing through the lungs may be arrested in other organs, notably the brain and the kidney. This accident is most common after a fracture of the long bone.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN.

THIRD DAY—JUNE 9TH.

(Continued from Page 1150.)

The Surgical Treatment of Bilocular Uterus and Bifid Vagina.—Dr. H. W. Longyear, of Detroit, stated that as this malformation was easy of correction it should, in his opinion, be operated upon as early as discovered, so as to avoid the accidents of pregnancy which are liable to complicate this anomaly of development. It was essential, however, that care be exercised in making a differential diagnosis between uterus duplex and uterus bicornis, for the only cases suitable for the author's operation were those in which a single uterus was divided by a medium septum extending to the fundus. The treatment consisted in grasping the septum between clamps, cutting along the latter with scissors, and then applying the Pacquelin cautery to the cut edges. The resulting cavity is then packed with gauze. Two cases were reported in which this procedure had been applied with success. One of these presented in addition an anomalous development of the left side of the body. In both there was also marked dysmenorrhea, which was apparently relieved by the operation, although in one it returned later on and necessitated oophorectomy.

Dr. Dunning, of Indianapolis, said that he had seen two cases of this kind, in which the septum was torn through during labor without any marked bleeding or other bad results. Both of his cases had done well and he doubted whether operative interference was necessary.

Dr. J. T. Johnson, of Washington, D. C., reported a case where a miscarriage for which curettage had been done, was followed by the birth of another fetus five months later. It was then determined that there was present a divided uterus, and if an operation had been done in this instance, the unpleasant consequences would have been avoided.

Dr. J. H. Carstens, of Detroit, also reported two patients. One of these had had several miscarriages, but after the septum was removed had a full term pregnancy. He advised the application of carbolic acid to the interior of the uterus after operation in order to prevent subsequent adhesions.

A Plea for More Thorough Examination of Doubtful Specimens of Ectopic Pregnancy.—Dr. J. W. Bovée, of Washington, D. C., claimed that, as many cases of ovarian and tubal hemorrhage had a symptomatology similar to that of disturbed tubal or tubo-ovarian pregnancy, particularly tubal abortion, the specimens removed from such cases were not carefully examined but were merely considered pregnancies. He suggested that for the sake of reliable statistics, if for nothing more, careful histological examinations should be made. He reported ten cases where the clinical history indicated a tubal pregnancy, but which on microscopical examination were found to be various other conditions, two of them in fact were malignant ovarian tumors.

Some Cases of Ectopic Gestation with Atypical Symptoms.—Dr. W. B. Dorsett, of St. Louis, found that occasional cases came under the observation of the surgeon that did not present the usual symptoms. Among others, right sided tubal pregnancies were sometimes mistaken for appendicular inflammations. Knowledge of the symptomatology was by no means complete. In some of the cases which he had operated, no diagnosis had been made, although indications were present which called for surgical interference. The history of the case should be subordinated to the general condition of the patient.

Dr. Carstens stated that he had operated on a case which he thought might be appendicitis. There was no temperature rise nor increase in the pulse rate. It turned out to be a right-sided ectopic. He believed that we should operate first and decide the pathological condition afterward.

Dr. Massey, of Philadelphia, entered a plea for more conservative measures in treating this condition, especially in those cases where the mass was already being absorbed by natural means. Where the diagnosis could be made of a tubal gestation, it was feasible to kill the fetus by the application of the electric current.

Dr. Goldspohn, of Chicago, considered that the only difficulty in diagnosis was in the cases seen before rupture had taken place. He also called attention to the fact that evidences of gestation were sometimes only found after a microscopical examination of the small cavity present in the interior of the blood clot. He did not believe that the peritoneum had any digestive function in doing away with the mass.

Dr. Dudley, of New York, believed that it was not necessary to remove the entire tube unless septic conditions were present. The fetus could be evacuated and the adnexa dropped back into the pelvis, after occlusions or other deformities had been corrected.

Others who participated in the discussion were Drs. Lawrence, Humiston, Stone, Brickner. The latter described the method in vogue at the Mount Sinai Hospital, in New York, in which a most careful menstrual history graphically worked out on a special chart, generally aided in making a diagnosis.

The Influence of Ovarian Implantation on Menstruation in Women.—Dr. A. P. Dudley, of New York, reported on seven cases in which he had done such conservative operations, all of which subsequently menstruated and were free from the physical changes or nervous manifestations attendant upon the production of the menopause. The last case he reported in detail. In this patient both tubes and one ovary had been previously removed. For the relief of her condition, hysterectomy was advised, but consent to do same was refused. It was then determined to free the cystic left ovary and implant it in the uterus. This was accordingly done, the organ being placed in a cavity prepared for it in the split horn of the uterus. Three months after the operation, the woman menstruated, and continued to do so at intervals of about three months. Eighteen months later a severe metrorrhagia began, for the relief of which it was finally necessary to do a total hysterectomy. The hemorrhage the writer was unable to account for. Examination of the uterus, which was presented at the meeting, showed that the uterine and ovarian tissue had become merged, with Graafian follicles well marked. In this as in the other cases, primary union had resulted between the uterus and the ovarian graft. Although he doubted the extended possibilities of the method, he thought that there was a field for its application and submitted the following questions for discussion: (1) Was the plan justifiable as a surgical procedure? (2) Was it worth the effort from a physiological standpoint? (3) Would the implanted ovary eventually resemble the fibroid in its action? (4) Was it possible that pregnancy might ultimately take place? (5) Providing it did, what was the prospect for normal delivery?

A Plea for Conservative Operations on the Ovaries, from a Neurotic Standpoint.—Dr. J. W. Cokenower, of Des Moines, Iowa, called attention to the necessity of making a better diagnosis in those cases which are referred to the gynecologist for a complex of symptoms, the cause of which is ascribed to ovarion lesions. It should be most carefully determined whether such symptoms were really due to the ovary. Intestinal intoxications could produce abnormal conditions of which pelvic disease might be the result rather than the cause. Neurotic cases were uncommon in which the condition was wholly dependent on diseased sexual organs. Negative results for ovarian operations undertaken for the relief of such troubles were quite common, and in making a decision it was best to hold an intermediate position. The time for concluding medical and beginning surgical treatment should be governed by the consensus of opinion of many observers, rather than the statistical reports of a few. He reported four cases to illlustrate his position, in which operation was followed by disappointing results.

Dr. Morris, of New York, told of his experiments with homoplastic and heteroplastic transplantations of the ovary in rabbits. Only the former was followed by successful results. He thought it well to save the ovary in pyosalpinx, and found that while the remainder of the operation was being carried out, the ovary could be kept in hot saline solution for a considerable length of time. In reference to Dr. Cokenower's paper, he thought also that it was most essential to differentiate carefully between fundamental psychoses and pure neuroses.

Dr. Goldspohn, of Chicago, said in discussing the second paper, that the problem of what to do in these cases could only be solved by making a better diagnosis between psychical and actual pain. In all patients it was well to examine all other parts of the body before the pelvis.

Dr. Humiston, of Cleveland, said that frequently the pelvic organs were normal, while others were at fault and probably accounted for the neurosis. Personally he only got good results from the radical ovarian operations.

Dr. Bacon, of Chicago, thought that the site of implantation was unfavorable, as the ovary might be washed away by the uterine discharges. It seemed to him that the chief object was to secure the benefits of the internal ovarian secretion rather the possibilities of pregnancy.

Dr. Massey, of Philadelphia, claimed that it was only necessary to remove the inflammation rather than the organ itself, and believed that this could be done most readily by kataphoresis with the mercuric ions.

Dr. Carstens, of Detroit, thought that the method might be of value in occasional cases in young women, but in older women it was necessary to extirpate the entire organ if the symptoms were bad.

Dr. Craig, of Boston, referred to the observation made by him that the normal ovary becomes scarred during middle life from the cicatrization of the continuously rupturing Graafian follicles. Many so-called cystic ovaries without clinical symptoms, are merely made up of such scarified ovaries with enlarged Graafian follicles. He considered that as it was necessary to keep up the internal ovarian secretion, Dudley's operation should prove of value.

Dr. Chandler, of Philadelphia, thought that the principal advantage to be gained from the operation lay in the fact that the menopause would be postponed. The objections were possible sepsis, death of the ovary, malignancy, and the action on the fetus.

A Series of Mistaken Gynecological Diagnoses.—Dr. T. S. Cullen, of Baltimore, presented five patients, in the first of which there were the classical signs of large multilocular ovarion cyst, but which on operation was found to be a pedunculated uterine fibroid, partially parasitic. The omentum was greatly atrophied. The association of this condition with ascites was referred to as very rare and unusual. In the second patient a diag-

nosis of globular uterus was made with two subperitoneal nodules. On section this was found to be an advanced adenocarcinoma of the corpus, although from the history it was not thought necessary to make a microscopical examination of the uterine scrapings. In the third patient there projected from the right side of the uterus a globular mass and from the vicinity of the right cornu a subperitoneal nodule. An intraligamentary and subperitoneal myomata were diagnosed. At operation the nodule proved to be a tense and kinked hydrosalpinx, and the intraligamentary growth an adenocarcinoma of the ovary, invading the bladder wall and the intestine. The fourth patient was a woman of sixty years, who had recently had temperatures from 100° to 103° F. There was marked pain in the pelvis and some discomfort during defecation. In the vaginal vault and apparently attached to the posterior surface of the uterus was a slightly irregular but globular mass. The diagnosis was either subperitoneal myomata with adhesions fixing it to the pelvic floor or a pelvic abscess. Operation disclosed an irregular globular tumor involving the sigmoid flexure. This had dropped over to the right side and become adherent to the pelvic floor. Between the growth and the floor of the pelvis was a small abscess due to rupture of a diverticulum from the intestine, of which there were a number filled with fecal concretions. In the fifth patient there had been present an adenocarcinoma of the kidney which had remained without recurrence for sixteen months after operation. Then a rapidly growing tumor of the liver was observed which involved the entire lower half. As determined later on, however, it was shown not to be a metastatic growth.

Injury to the Rectum in the Gynecologic Examinations.—Dr. H. A. Kelly, of Baltimore, in calling attention to the importance of the rectum as an avenue of investigation, referred to the dangers attending an examination roughly conducted. It was possible not only to rupture cystic structures and to spread their contents all over the abdomen, but also to injure the rectum itself. He saw four cases where the examining finger had been pushed through the rectum, and in one instance had entered a large ovarian cyst. It was not always the examiner's fault, and some of the blame might be placed on the soft condition of the tissues. In making rectal examinations it was always well to recognize but not invaginate the ampullæ, and to get the finger well beyond what he described as the third sphincter. The arm should always be relaxed and the wrist loosely held. The bowel when distended with air facilitated the examination and if the patient were in the dorsal position, the air escaped much more slowly than in the Syms position. Repair may be done through the posterior cul-de-sac, or by abdominal section.

Drs. Cullen, Lawrence, Shoemaker, Wetherill, and Noble all reported instances of rectal injury sustained in this manner.

Some Further Observations on the Use of the Stem Pessary for Scanty and Painful Menstruation.—Dr. J. H. Carstens, of Detroit, said that he had relieved many cases by this method. There were two classes of patients, young girls who had always been troubled by their menstrual flow and who had been subjected to continuous overstudy, and others, where the dysmenorrhea came on later, after a normal menstruation had been present for some years. These were unmarried women in whom the uterus and particularly the cervix were undergoing premature atrophy. The condition he claimed was due to the lack of development of the uterine muscle, and the only way to develop it was by exercise. This he believed could be secured by the introduction of a foreign body which the organ constantly endeavors to expel. The stem pessary was the most suitable means. He reported several cases. In one the stem had been in place for two years with relief of symptoms, but on removal the condition gradually returned and the stem had to be reintroduced. One case would not tolerate the stem and promptly expelled it. One case of sterility of five years had now become pregnant after the use of the stem for a few months.

The Propriety, Indications and Methods for the Termination of Pregnancy.—Dr. F. A. Higgins, of Boston, presented this paper in which he stated that there were evidences of broadening in the indications for the termination of pregnancy. The wisdom of this could not be questioned and the only after thought would be the possibility that it might lead to ill advised abortion. This he doubted. He then discussed the various acute and chronic diseases which might determine abortion. Acute diseases are not usually an indication unless labor intervenes; if so, the latter should be expedited. In treating of the various methods he thought that if bougies were used, the employment of two was better than one. He recommended the Voorhees bag and the colpeurynter however. Manual dilatation might cause rupture, while instruments were safer and under control. The dilatation depended upon the amount of stretching which the cervix would endure. The author's new form of dilator was presented and compared with the Bossi instrument, an example of which was also at hand.

Dr. Hall, of Kansas City, thought it was more honorable to suggest methods of preventing pregnancy in doubtful cases rather than to devise methods of abortion. The effect of such a paper might be bad on the public mind. But where indicated, he believed the use of a suitable instrument preferable to the finger.

Dr. Bacon, of Chicago, believed that the social condition of the patient had much to do in deciding the question. In twins and hydramnion, rupture of the membranes was indicated and he preferred that the dilating bag should be within the egg sac. Vaginal Cæsarean section was to be preferred to the use of instrumental dilatation.

Adherent Uterus as a Complication of Labor.—Dr. J. C. Applegate, of Philadelphia, based his paper on the question as to what circumstances should permit the pregnant woman with an adherent uterus to go to term. In his experiences with the various methods of operating he found that the round ligament methods had no effect on the pregnancy, but that labor destroyed the results of previous operation. The Montgomery seemed to be the most suitable. Peritoneal suspension was dangerous from the possibility of rupture of the uterus. Ventral fixation was unjustifiable before the menopause except in rare circumstances, and pregnancy to full term depends entirely on the mobility of the uterus. If the cervix did not enlarge and rise posteriorly, labor should be induced. Cæsarean section is the safest procedure in these cases. The most favorable method in his experience had been hysteropexy, with the sutures introduced in front of the origin of the tubes instead of to the fundus.

Drs. Craig, Shoemaker, Dunning, Dorsett, and Fry discussed this paper and reported cases of labor after operation.

Membranous Endometritis.—Dr. F. F. Lawrence, of Columbus, called attention to the unsatisfactory result obtained with local treatment in this condition. In a series of 42 cases examined by him, he noted that tubal or ovarious disease was present in a large proportion of cases, a considerable number of which had followed

the exanthemata. He believed that the disease was due to a secondary trophic change dependent upon an intercurrent pelvic disease. Where the condition of the ovaries and tubes was not due to an immediate infection, he believed that the endometritis could be cured by excision of the diseased structures without treating the uterus itself. He presented several successful cases and recommended that in all cases of membranous endometritis, a careful pelvic examination be made and that the method suggested be given a further trial.

Dr. Fischer, of Philadelphia, expressed surprise at the large number of cases seen by the author, but considered that those cases in which shreds only were passed should not be included in the classification. Drs. Dunning and Bonifield had also seen but very few cases of this condition.

Officers of the Section for the year 1904-1905.—Chairman, Dr. C. L. Bonifield, of Cincinnati; Vice-Chairman, Dr. F. F. Lawrence, of Columbus, Ohio; Secretary, Dr. W. P. Manton, of Detroit, Mich.; Delegate, Dr. J. W. Bovée, of Washington.

SECTION ON PEDIATRICS.

SECOND DAY—JUNE 8TH.

(Continued from Page 1150.)

How to Produce the Best Milk for Artificial Infant Feeding.—In this paper Dr. Edward F. Brush, of Mount Vernon, N. Y., called attention to the importance of cleanliness in both the surroundings and in the food provided for the cow which is to produce milk for infant feeding, and emphasized the fact that mental and physical conditions greatly affect the quality of the milk produced, and said that the mixed milk of a herd is greatly superior to milk from one cow which, he said, is always dangerous, that thoroughbreds and large producing varieties generally are usually the most liable to be affected with tuberculosis. Many cows, he said, might be safe enough for the production of butter and cheese, but at the same time might not be good producers of milk for the infant. Dr. Brush related personal experiences showing that a single cow may at times be apparently well and yet may cause the death of infants fed upon her milk. He did not believe in modifying milk other than by the addition of sterile water and, if necessary, cream. Milk, he said, should be reduced in temperature, soon after milking, to 50° F., and kept there till used, but of greatest importance was the gentle treatment of all cows, for experience had taught him that an irritated cow will produce milk which will cause illness in the baby fed upon it.

The Initial Contamination of Dairy Milk.—In discussing this subject Dr. Richard Cole Newton, of Montclair, N. J., said that one of the most encouraging signs of the times is the interest and knowledge among the laity concerning all matters pertaining to hygienic living and particularly of dairy methods. It is popularly believed that milk is aseptic while in the cow's udder, but this had been disproved by Kahn, who after most careful and elaborate attention to asepsis and antisepsis had found that cow's milk in the udder contained 242 bacteria to the cubic centimeter. Cow's milk, he said, is most frequently contaminated with dung which dissolves in the milk but carries enormous numbers of bacteria with it into the milk and that experimentation had shown that one-third of a grain carried with it seven million bacteria. Pure milk, he said, should be odorless and should have so slight a taste that most people would pronounce it tasteless and that the microscope would not detect all the contamination of milk nor would the Pasteur filter remove it. Many methods had been tried in the effort to remove the initial contamination, with greater or less success and he described various milk pails which had been devised to prevent the contamination which occurs at the time of milking, at which time the greatest amount of dirt enters the milk and that the bacteria which enter the milk afterward multiply more rapidly than those which are present before withdrawal from the udder and, therefore, if these secondary bacteria are kept out the milk will keep in good condition longer than otherwise. The method recommended for prevention of initial contamination was to cover the milk pail with sterilized cheese cloth and to draw the milk directly from the udder through this into the pail which had, of course, been previously boiled, then bottled and reduced at once to a temperature below 50° F. Such milk should not contain over 5,500 germs per cubic centimeter. This method was available to any farmer, and he should be encouraged to adopt it.

Dr. J. P. C. Griffith, of Philadelphia, said that simplicity in the care of milk is of paramount importance; that Pasteurization and sterilization are useful but only when other means of obtaining good milk were not possible. He said that the added cost of milk properly obtained was an objection, but that it was worth the added cost. The Philadelphia Pediatric Society, he said, granted certificates to dairies which kept the number of bacteria per cubic centimeter below ten thousand.

Dr. F. L. Smith, of Bridgeport, Conn., said that milk is very frequently rendered poor by improper food being given to the cows and that the Jersey cow is most susceptible to poor food. He mentioned as an example of this a case in which a herd of Jerseys had fed upon partially decayed apples, after which five of them had become drunk, and said that surely milk from such a herd was not proper food for infants. It was a well-known fact, he said, that milk frequently tasted of the food which had been eaten by the cow and that the farmer should be educated along the lines suggested by this idea.

Dr. L. C. Ager, of Brooklyn, said that every time milk is handled it is endangered and that in recognition of this the Brooklyn authorities had recently instituted a change whereby all milk is bottled at the farm and not at the creamery, and that this had resulted in the sale of better milk. Difficulty, he said, had been found in compelling the dealers to conform to the requirements of the Brooklyn authorities as they had been found placing certification labels on poor grades of milk.

Dr. Southworth, of New York, said that he did not agree with Dr. Brush in that he preferred milk sugar to cane sugar when it became necessary to add sugar to milk. He said also that the time has passed when we thought we could make cow's milk equivalent to mother's milk and that the importance of the situation would be more nearly realized if we should call the child's condition a pathological one when it is removed from the mother's breast. He said that he believed in Pasteurization and sterilization when we have milk that has not been properly secured or is somewhat old, although he recognized the disadvantages of milk so treated.

Dr. Morse, of Baltimore, said that efforts to render milk free from initial contamination were important, but that proper modification of milk should not be neglected and said that he, too, preferred milk sugar to cane sugar for addition to milk in its modification. He asked Dr. Brush what should be the cost of good milk.

Dr. Hamill, of Philadelphia, said that investigation

of the actual cost of producing good milk in Philadelphia had shown that seven and three-quarters cents per quart was the minimum cost per quart. He said that a milk pail similar to the one advocated by Dr. Newton was in use at the dairies near Philadelphia.

Dr. Gilbert, of Louisville, said that he had had very good results from sending sick children and infants to places where they could get milk while it was still warm with the animal heat of the cow.

Dr. Brush, in closing, said that he wished to emphasize the importance of obtaining milk from cows which had been gently treated. This, he said, was of even more importance than the exclusion of contaminating materials. He said that he preferred cane sugar in treating milk because experimentation had proved to him that milk sugar is practically inert, and because the commercial milk sugar is not pure. The cost of producing milk, he said, was about six or seven cents per quart and that the best milk is worth on the market from fifteen to twenty cents per quart. He further said that raw milk had always proved preferable to modified milk in his experience and cited cases to support this statement.

Dr. Newton said that, contrary to popular belief, milk which has undergone lactic acid fermentation was not necessarily bad and that "sweet" milk was not always good. The lactic acid bacteria tend to inhibit the action of other bacteria and may therefore be beneficial. In regard to sterilization, he said that when he had fed mice on sterilized milk exclusively they had died at the end of twenty-five days. He endorsed Dr. Brush's advocation of the gentle treatment of cows as productive of a better quality of milk.

Chronic Constipation in Infants.—Dr. J. Ross Snyder, of Birmingham, Ala., defined constipation as "any condition in which products of food are retained in the bowel after they have lost all nutritive power" and then went carefully over the conditions which tend to produce this result in the infant. The abdomen of the infant is such that it conduces to the accumulation of waste products in the bowel, since the lumen of the intestine is proportionately smaller than that of the adult and also longer, while the pelvis is smaller. This, he said, causes a distention of the abdominal wall and unless food such as the infantile digestive organs can care for is given to the child constipation follows; that some have thought that constipation in the mother produces an inherited tendency to constipation in the child, but this he said is not true; that although the child of a constipated mother might be more liable to constipation it was due to altered milk secretion due to improper food taken by the mother and later in the child's life to the subjection of the child to the same improper alimentation and lack of proper conditions from which the mother suffered. Tight diapers and other causes of pressure upon the abdomen are factors also in the production of constipation as are irregular and overfeeding, lack of bulk or the proper amount of fats, but the most constant cause is improper diet and in treating the condition this should always be borne in mind. The alleviation of constipation by drugs, while necessary, should not be the object of treatment as the cause should be eradicated and this could almost always be done by attention to the child's diet. Suppositories, injections and similar measures are to be discountenanced and massage of the abdomen should never be used in the treatment of constipation of infants.

Dr. I. A. Abt, of Chicago, said that the prevalent idea of fats in the production of constipation is erroneous and that occasionally there exists a tonic spasm of the sphincter and muscle which may be overcome by the introduction of a clinical thermometer into the anus.

Refractive Errors in Children.—Dr. J. H. Claiborne, of New York, reviewed the forms of these conditions which produce eye-strain, noting four general conditions, the ametropic eye, the hypermetropic eye, the myopic eye and the astigmatic eye. He condemned the custom of putting too much work upon the growing child and particularly in the condition in which the association of the extrinsic eye-muscles with the faulty refractive condition in the attainment of single binocular vision is productive of symptoms of eye-strain. The evidences of eye-strain, he said, are headache, frontal or occipital, irritability, nervousness, lack of concentration, etc., and that so clearly does the child show the signs of eye-strain in its face that an experienced ophthalmologist can almost always diagnose the form of refractive error by the expression on the face of the patient. In reviewing the conditions considered at various times as the result of eye-strain, he said of migraine that it could always be modified by correction of refractive errors and many times it might be prevented, of epilepsy and insanity he said that he did not believe it could ever be cured in this way nor could paresis or paralysis be influenced. Hysterical manifestations may be modified but only by distracting the attention of the individual from the point of numbness or other abnormal condition which may be present. He did not believe that the chorea of Sydenham was ever cured by glasses, but many cases diagnosed chorea are merely cases of eye-strain in which the efforts of the patient to secure single binocular vision are productive of facial contortions which resembled the twitchings of chorea. These, of course, could be influenced by the proper treatment of ocular errors. A frequent cause of nausea and other digestive disturbances, he said, is eye-strain, and any child that has these disorders or is not up to the average in its work in school or elsewhere should be examined for refractive errors. In conclusion Dr. Claiborne said that (1) nervous symptoms of a variety of kinds occur as the result of eye-strain. (2) Eye-strain is due to refractive errors, to imbalance of the external ocular muscular system, or more frequently to a combination of the two. (3) Of these two the refractive errors are by far the more frequent cause. (4) Muscular imbalance alone may cause it. (5) Headache is by far the most common nervous symptom caused by eye-strain. (6) The headache is chronic or induced directly by near work and is generally in the forehead and temples. (7) Migraine or hemicrania due to eye-strain is comparatively rare in children. (8) Any nervous symptom in children should arouse the suspicion of ocular defects either as a direct or contributive cause. (9) Correction should be made under atropine.

(To be Continued.)

SECTION OF MATERIA MEDICA, PHARMACY AND THERAPEUTICS.

FIRST DAY—JUNE 7TH.

Dr. O. T. Osborne, of New Haven, the Chairman, delivered an address entitled "The Scourge of Nostrums and Irregular Practitioners." He made some very pointed remarks bearing upon this subject.

Federal Supervision of Drugs.—Dr. H. W. Wiley, of Washington, D. C., spoke of the steps which the Department of Agriculture had taken in establishing a laboratory for the study of drug adulterations. By this means importation frauds can be more easily detected and a means afforded for the formulation of a uniform standard of duty. He further referred to the organization of a drug laboratory in the Bureau of Chemistry for the study of foreign drug plants with a view of in-

troducing them into this country for cultivation. The cooperation of the Post Office Department in excluding fraudulent preparations from the mail was praised. He expressed the great desirability of obtaining the cooperation of the pharmaceutists in doing away with all drugs of unknown character and strength.

SECOND DAY—JUNE 8TH.

Relation of the Internal Secretions to Epilepsy, Puerperal Eclampsia and Kindred Convulsive Disorders.—Dr. C. E. Sajous, of Philadelphia, gave a brief review of the adrenal system and its functions; the pathogenesis and pathological anatomy of the above and kindred diseases together with a study of their mutual relationship. Forms of treatment suggested by the clinical experience of the writer were outlined.

Hypnotic Drugs in Mental Disease.—Dr. Alfred R. Defendorf, of Middletown, Conn., reviewed the common hypnotics in which he pointed out their respective values in the correction of the condition which indicated their use. He showed clearly how the physiological action differed with the nature of the drug.

Chronic Arterial Hypertension.—Dr. H. W. Cook, of Richmond, Va., read a paper discussing those vascular diseases which involve hypertension. He reviewed its relations to arterial sclerosis, chronic nephritis and similar diseases. Alcohol does not produce hypertension by any action of its own, but only by chronic productive inflammation in the various vascular organs of the body, whereas toxins and toxic chemicals and drugs produce an increase in tension by constriction of the vessels themselves. He spoke of an idiopathic hypertension sometimes found, the cause of which is not apparent even on careful examination. The treatment suggested was vasodilatation. This relieves the condition of hypertension only and does not cure. The nitrites, especially amyl, and sodium nitrites seem to be the most serviceable. Nitro-glycerine is uncertain in its action. Sodium nitrite has been found to lower tension for from two to four hours. The best results follow doses of one to two grains after meals. The latter has many other advantages over nitroglycerine. The transient character of the action of the nitrites was brought up in discussion, but it was held by the author that the action of the sodium nitrite is sufficiently prolonged to furnish satisfactory results in chronic cases.

Control of Internal Hemorrhage by Drugs.—Dr. T. L. Coley, of Philadelphia, said this included all forms of hemorrhage in which the bleeding points could not be reached. An important factor set down was the need of absolute bodily mental rest in cases of internal hemorrhage. The patient's great fear of the results of the hemorrhage should be controlled to aid vasodilatation, so as to decrease blood pressure. He spoke of the danger from the dislodgment of clots, by increasing the blood pressure with the stimulants administered for shock. In reviewing the various internal hemostatics now in general use, he held there was no evidence of their value as local vasoconstrictors. Adrenalin has value only when used locally. Its internal administration is contraindicated, since it has no selective action. Digitalis and ergot also are contraindicated, the latter, especially in pulmonary hemorrhage. Opium and morphine have proved of the greatest value for all forms of bleeding by their general depressing action. Ipecac has been shown to be a specific in some forms of dysentery, but the emesis it produces does not permit its use in pulmonary hemorrhage. Strychnine is only indicated in careful doses when collapse is imminent. Alcohol has no value. Normal saline solution by enteroclysis and hypodermoclysis gives the best and quickest results. While calcium chloride is good, its prolonged use may be followed by a reverse in its action. The use of gelatin by injection is uncertain, though it should not be discontinued. There is not a single internal hemostatic that is specific. Discussion brought out the great clinical value of atropine, although it is theoretically contraindicated.

Drugs Irritant to the Kidneys.—Dr. Torald Sollman, of Cleveland, said that too little is known about this class of drugs. He showed the great need of experiments, both clinical and on animals, to determine to what extent the drugs falling under this head could be used without an increased impairment of the kidneys' excretory process. He added that a drug might be serviceable even if it irritated renal epithelium if it aided in the excretion of toxic substances.

Newer Physiology of the Gastro-intestinal Canal.—Dr. L. B. Mendel, of New Haven, Conn., reviewed recent important works on this subject. He declared there was a difference between the peristaltic action of the cardiac and pyloric portions of the stomach in the digestive process, that of the cardiac region being the more active. The pylorus is stimulated to rhythmical contraction by the presence of free acid in the stomach. He spoke of the recent idea in regard to the stimulation of the digestive glands. It is thought that the quantities of the various enzymes secreted differ according to the character of the food ingested, a larger quantity of a proteid food causing an increase in the secretion of the proteolytic enzymes and vice versa. He likened it to a physiological education of the digestive glands. Presupposing these principles, the disuse and misuse of a gland are very important. He discussed the mechanism and enervation of the elementary canal and the chemical changes therein.

Etiology and Pathology of Gout.—Dr. T. B. Futcher, of Baltimore, said heredity was a very important factor in the etiology of gout. The disease is more frequent in males than in females. Alcohol in the non-distilled beverages is a more important factor than in the distilled liquors. Large amounts of nitrogenous food associated with bad hygienic measures are predisposing factors. Lead intoxication may be a cause. Gout is common in saloon keepers and brewers. It is accompanied by an excess of uric acid, which is supposed to be due to a deficient excretion by the kidney of nitrogenous materials. The condition is probably due to the circulation of the uric acid in the blood and its subsequent deposition in that part of the peri-articular cartilages farthest from the vascular supply. The alkalinity of the blood is not decreased.

Systemic Value of Radical Changes in Diet.—Dr. R. H. Chittenden, of Yale, reviewed a series of experiments conducted at New Haven during the past winter on 26 males. They represented all sorts and conditions of men. He said that heretofore experiments had dealt with the fact that people thought man required a certain amount of nitrogenous food. The results from his experiments showed that a reduction of nitrogen was beneficial rather than deleterious. He argued that if the body could get along with less nitrogenous food, the excretory tissues would not have to do as much work and they would obtain physiological rest. Must there not be some value in the resting of these processes? There is perfect safety in a lower nitrogenous diet. Subjects of the experiments did not lose weight, blood or strength, but gained in all of these. He ascribed some benefit to a more regular mode of life and exercise but made due allowance for these factors in his conclusions. The writer believed there was a gain by the physiological economy and this would relieve the kidneys and liver. He believed in a diet which decreased uric acid or its precedents, in temperance—not in prohibition.

Third Day—June 9th.

Hydrastis, Some of Its Therapeutic Uses.—Dr. Blair Stewart, of Atlantic City, gave a brief historical sketch of the drug, and described its physiological action. He gave his experience with the drug which he found valuable in catarrhal conditions of the gastro-intestinal tract. He found the best results to follow very small doses given at frequent intervals. For colitis, he recommended one to six drops of the fluid extract in water before meals and cautioned those using it against prescribing it in cases of pregnant women.

Apocynum Cannabinum.—Dr. Horatio Wood, Jr., of Philadelphia, reviewed the uses of the drug and its literature. By careful pharmacological experimentation with the drug, he found its principal action was the following: It caused the heart to beat slower and stronger, and increased the blood pressure markedly. The heart regained its normal beat, but maintained a high vascular pressure. There is a rapid fall in the pressure following its discontinuance. He found the action to be due to a stimulation of the inhibitory center in the medulla, the cord not entering into the process. He compared and contrasted its action with digitalis, with which its action is quite similar. It has a pronounced diuretic action dependent upon the increased pressure. In seeking its active principle, he was led to believe that it is in the form of a glucoside. Unfortunately he has not as yet been able to decide the question.

The Specific Treatment for Tuberculosis.—Dr. Edward R. Baldwin, of Saranac Lake, N. Y., said his conclusions were drawn from experiments on animals and clinical observation. He said that he was led to believe that tuberculin acted by immunizing followed by a healing process. He found that it had very questionable value in the more acute conditions or in advanced stages of the disease. He did not discountenance its use, however, as a matter of resort, but said that it was of great value in clearing the sputum of bacilli and in completing the physical cure in chronic incipient cases; especially those cases which although apparently cured, resist the efforts of the physician in bringing the patient to that stage where he can be safely discharged from observation. The most rational tuberculin, he thought, was prepared as an emulsion of the bacilli sterilized by chemicals and not by heat, as the heat causes a destructive process. He believed that the treatment should be given periodically, with intervals of three months. The great care required in the administration and supervision of its use limited it to sanatoria. He considered any serumtherapy which has been produced to be of no use in the treatment of tuberculosis.

Progress in Actinotherapy.—Dr. William S. Gottheil, of New York, said that its use by reason of the expense and the character of the apparatus was limited to hospitals and sanatoria. He reviewed the various forms of ray and declared much had been done in the way of cures by the use of this form of treatment. A large part of the lack of success met with could be accounted for by the lack of strength of the light. The ordinary Finsen apparatus cannot be obtained in this country. The average machine sold in this country is entirely too weak to do much good, as only the very highest powers produce results, *i.e.* arcs of 50 to 100 amperes. He found the deeper results to vary inversely as the superficial ones.

Internal Medication and External Application in Pneumonia.—Dr. George Dock, of Ann Arbor, contrasted the value of the more common internal methods which had been in use for so long, with the more recent and simpler ideas. He called attention to the necessity of keeping the mouth as aseptic as possible and said that the usual bronchial and intestinal complications are best treated by means of internal medication, whereas, the best all round routine treatment for the heart and cerebral symptoms is the ice coil, ice bag, or ice bath. Although seemingly a method which is too radical, the rapid and positive relief following their use demand it from the physician.

Heart Failure in Pneumonia.—Dr. Solomon Solis-Cohen reviewed and classified the causes of heart failure as a complication and emphatically called attention to the point that the time to treat heart failure was before the failure appeared. The toxemia calls for free blood letting and diuresis. In the first stages of the disease, heat should be used to obtain diaphoresis, the rationale being to get rid of the toxins; while venesection is indicated in the latter stages for the same purpose, when the vascular system becomes weakened. Some of the more common causes of heart failure are febrile heat and its treatment, with antipyretics and cold, toxemia eliminating measures, and deficient oxygenation of the blood. He advocated the use of tincture of musk, drops five to ten, by mouth. The purity of the drug must be positively ascertained. He laid special stress upon the application of cold. If the ice-bag or coil is preceded for a minute or two by intense heat, the shock of applying the cold is diminished and the result is better. The time for the application of cold is ten to thirty minutes twice a day, or as the heart symptoms indicate. As poultices do relieve pain and give rest, they should be used. Absolute rest of the patient on his back in a passive condition is essential. The least movement is to be prohibited. Amyl nitrite and nitroglycerin are great aids in the congestion of the pulmonary circulation. The treatment could be summed up in the use of good judgment, conservatism and the immediate execution of indicated treatment.

Serum Treatment of Pneumonia.—Dr. J. M Anders, of Philadelphia, said it was the most rational treatment of the disease. Success has followed its use by some, failures by others. He showed the need of a more effective preparation and called attention to the necessity of a bacteriological diagnosis in pneumonia before the use of serum treatment could be carried out properly. The statistics of its use so far are of no value, as they deal with isolated cases. With those cases reported, the results have not been as good as when the patient was treated in the usual way. Summing up the ordinary treatment, its trial has been of sufficient duration to prove that it is no good, and that there is a field for a good toxin yet to be found.

Therapeutic Value of Massage in Acute Diseases.—Dr. J. W. Seaver of New Haven, Conn., reviewed the anatomy of the hemic and lymphatic circulations in both the deep and the superficial tissues, and endeavored to show the theoretical basis for the use of massage. He discussed at some length the wide field for its application and those diseases which would be most apt to respond to its use. He made a strong plea for a system of instruction in this country similar to the institutions in Sweden for the education of skilled masseurs.

IODINE AND MERCURY TO COMBAT LOCAL INFECTIONS.

BY AUG. STABLER, M.D.,

OF BRIGHTON, MARYLAND.

WHEN the germ theory was in its infancy, Koch determined that mercuric iodide stood at the head of the list of the germicides then known, being capable of killing anthrax and other bacilli in the dilution of one part in 50,000 parts of water.

It is well known that the human system may be permeated by small quantities of either mercury or iodine without causing any unpleasant symptoms. When a patient has been taking potassium iodide in full medicinal doses, if calomel be dusted on the conjunctiva, a red color will be developed with coincident irritation due to the formation of mercuric iodide. Calomel being an insoluble substance the iodide of mercury is in this case developed on the surface of the mucous membrane and at first produces only a surface disinfection, but mercuric iodide being soluble in solutions containing potassium iodide, will penetrate more or less deeply and kill or inhibit some of the microbes imbedded in the tissues. If, instead of potassium iodide, the calomel be given internally in moderate doses frequently repeated, and a solution of iodine be applied locally, mercuric iodide will again be formed, but iodine being a diffusible substance and mercury being contained in the fluids of the body the penetration will be deeper and the local irritation less than when the calomel was locally applied.

This consideration led me about ten years ago to formulate and put in practice a general method of treating local infections, which has given most gratifying results in a great number and variety of clinical cases. The solution of iodine which I apply to mucous membranes is as follows: A menstruum is made of equal parts of glycerin and water. To this I add tincture iodine one dram to the ounce with a little belladonna and carbolic acid as local sedatives. This stock solution, which can be made up in a few minutes, from materials that every physician can carry, is applied through a simple hand atomizer to throat and nose, if these are the parts requiring local treatment, or it may be applied to uterus, vagina urethra or skin in any way the physician desires.

In using the atomizer I always direct the patient to hold the tube between the teeth with lips closed in the same position as in smoking a pipe and to *breathe through the nose*. The bulb is worked vigorously and the fine spray will be seen issuing from the nostrils, showing plainly that the whole interior of throat and nose is covered with the spray. If the mouth be open while spraying the spray strikes the posterior wall of the pharynx and flies back out of the mouth without reaching the postnasal space at all. Even small children readily learn to "smoke a pipe" in this way and may have their throats pleasantly and painlessly disinfected many times a day.

In February, 1899, when the snow was 2½ feet deep on a level and drifted to six feet in all the roads, I was called to a house three miles from home wherein I found a father, mother and fifteen children (negroes) living in four rooms. Five of the children had diphtheria. It was the middle house in a row of small tenements and the family was receiving frequent friendly visits from near neighbors on either side. The infection was traceable to a previous case of diphtheria about a mile away where one of the children had been staying.

Owing to the impassable roads no antitoxin could be obtained and I quickly resolved to give my method a thorough test. The calomel was commenced at once and a messenger despatched for an atomizer and a pound of formaldehyde solution. The mother was directed to spray the throats with iodine solution every two hours and each time to pour a little formaldehyde on the hot stove. Communication with the outside world was cut off as far as possible both by telling the family and warning others of the danger. The effect of treatment was very marked within the first twenty-four hours. Even the baby three months old took it well, and all progressed favorably to recovery without a single complication. Two new cases developed in the family and these also were successfully treated. There was no spread of the infection to other houses.

In several of these cases I found that when the calomel was pushed the false membrane would clean off when the iodine spray alone seemed to have little effect. Of course, now, I always use antitoxin at the earliest possible moment and take pains to keep a fresh supply on hand, but this does not kill the bacillus of Loeffler, or prevent it from being carried for weeks or months in the throat of a recovered patient. By using antitoxin, mercury and iodine simultaneously, the enemy is attacked in front, flanks and rear, and the only terms are unconditional surrender.

Rheumatism is another infection now generally believed to enter by the tonsil and the painful condition of the tonsil always gives warning of its presence. Here the mercury and iodine achieve brilliant results, and if applied early, suppuration of the tonsil, and joint and heart complications rarely occur. When called to a case of acute articular rheumatism (even if gonorrheal), it is my practice to apply an iodine

plaster to the affected joint. A piece of Z. O. adhesive plaster about six by eight inches has a thin layer of absorbent cotton or lint spread on the sticky side leaving a margin uncovered about 1½ inch wide all around. The cotton is moistened with tincture iodine, tincture belladonna and spirits of camphor, equal parts. The plaster is warmed, applied and covered with flannel. If the pain is not controlled in twenty-four hours I raise one edge of the plaster and pour in more of the solution, covering the leak with a fresh piece of plaster; not forgetting to push the mercury internally and also give a little acetanilid and salol. Morphine is very seldom needed where this treatment is begun early. Even in sciatica these measures have given me better results than any other treatment.

Subcutaneous infections, such as boils, carbuncles, phlegmons, felons, etc., are treated with the happiest results. Here I usually combine ichthyol and tincture iodine of each one part with six parts of boroglyceride. Apply on lint or absorbent cotton and cover with parchment paper and a bandage. The same treatment is very effective in erysipelas and in mammary inflammations. In local infection of the uterus occurring after abortion or parturition this method has given excellent results. Being harmless and painless the solution may be injected directly into the uterine cavity with a hard rubber syringe having a long slender nozzle. The depleting action of the glycerin is here a valuable adjunct. Where the cervix and vagina only need treatment the patient may be trusted to make the applications herself, as but a teaspoonful of the iodine, ichthyol and boroglyceride injected into the vagina and left there two or three times a day, is sufficient. I have not yet given the method sufficient trial in chronic skin diseases but believe it will have a field of usefulness in acne, eczema, tricophytosis and other intractable affections.

In writing this paper I have directly violated the advice of my revered professors, given twenty years ago: "Avoid routine practice. Treat patients, not disease." But we are surely progressing toward specific treatment for infectious maladies. An enlightened public and the physician's own conscience demand that he be an aggressive fighter, prepared and striving to *cure* disease whenever possible; frequently successful in arresting invasions that soon would be beyond control.

Spleen in Pernicious Anemia.—In a number of cases of pernicious anemia examined by O. Kurpuweit (Deutsch. Arch. f. klin. Med., Vol. 80, Nos. 1 and 2) the spleen was not enlarged. Microscopically, elements were found, which are not usually described, namely cells characteristic of the bone-marrow, such as neutrophile and eosinophile myelocytes, normo- and megaloblasts. The spleen was then examined at a number of other autopsies, with the result that eosinophiles, myelocytes and normoblasts were encountered wherever the spleen was altered through congestion, inflammatory processes and severe anemia. Since these cells normally do not belong to the spleen, it is safe to assume that the splenic tissue can easily undergo myeloid transformation.

A BRIEF REPORT OF FOUR YEARS OF GENITO-URINARY WORK IN THE SECOND SURGICAL DIVISION OF MOUNT SINAI HOSPITAL.

BY HOWARD LILIENTHAL, M.D.,
OF NEW YORK.

(Continued from Page 1166.)

Until our results are less satisfactory than they are at present suprapubic prostatectomy will be our method of choice. Although portions of the urethra have come away with the prostate in some cases, the writer believes that with care and not too great haste this may almost always be avoided.[1] The operation is rapid, comparatively bloodless, and is followed by a minimum degree of shock. It permits of a quick and accurate examination of all portions of the bladder with the removal of calculi even when they are encysted. Wounding of the rectum is very rare, and has not occurred in any of our cases. The wound heals within three or four weeks, the function of urination returning sometimes as early as the tenth day. Impotency rarely if ever follows. Believing that the technic of the operation has very much to do with its success, I will give the steps in a few words:

1. Passing of catheter and washing the bladder, leaving the viscus empty, and attaching a rubber atomizer bulb to the catheter.

2. Incision 2 or 2½ inches long, in the linea alba with retraction of the recti.

3. Inflation of the bladder by an assistant. (There being no ligature about the penis, there is no dangerous air tension so long as the catheter is not very large. Besides, the finger of the operator in the wound would at once detect dangerous pressure.)

4. Retraction of the peritoneal reflection.

5. Insertion of two retraction sutures into the vesical wall.

6. Puncture of the bladder with a narrow-bladed knife and the enlarging of this opening with the dressing forceps. (Thus far about a minute to a minute and a half may have been consumed, without any appearance of haste, provided careful preparation has been made for each step.)

7. Exploration of bladder and palpation of prostate.

8. An assistant places his finger in the rectum and pushes up the prostate which is now caught firmly with bullet forceps or vulsella.

9. A sagittal incision of the mucosa and prostatic substance with scissors.

10. Enucleation of the organ with the ungloved finger. (One need not hurry during this important step of the operation. It is better to work a little slowly than too roughly or carelessly. The entire procedure will be found to have consumed not more than say from ten to fifteen minutes.)

11. Thorough flushing of the bladder through the wound with hot saline solution.

12. Packing of the prostatic portion of the

[1] The writer does not believe that the urethra should be removed by preference, in spite of the good showing of Moynihan. Annals of Surgery, Jan., 1904.

wound through a very large endoscope or a Kelly's cystoscope inserted into the wound.

We have found the perineal drain to be unnecessary and, if anything, a detriment. Careful continuous siphonage with frequent flushing of the bladder answer every purpose. For the first thirty-six to forty-eight hours after the operation the packings are left in, the gauze upon the abdomen being changed as often as it becomes saturated. Then the packings are removed, the tube is inserted and siphonage begun.

Very old or feeble individuals, in whom the danger from pulmonary hypostasis is great, may be allowed to sit up out of bed on the third day, the siphonage being temporarily interrupted.

There is no time here to go into the matter of preparation for the operation, the proper selection of cases and many other interesting and important points.

In the matter of carcinoma of the prostate, I must say that I cannot agree with Harrison, who considers it bad surgery to curet suprapubically. On the contrary, I have given much relief in these cases and believe it to be justifiable and surgical.

Case XI.—Vesical Calculus; Prostatic Hypertrophy; Suprapubic Lithotomy; Prostatectomy; Cure.

Joseph S., aged seventy-seven years, had never had any genito-urinary disease. For years there had been frequent urination at night. There was an attack of cystitis with retention some months before admission. Since then urination consisted merely in overflow unless the catheter was employed. There had been a left epididymitis, hematuria intermittent in character, and spasm of the vesical sphincter frequent and severe. Soft rubber catheter entered with difficulty and a Mercier not at all, because of the sensitiveness of the deep urethra. The circulation was sluggish as shown by edema of the legs and ankles. There was no valvular cardiac disease, but some senile myocarditis. Urine was apparently normal so far as renal elements were concerned, but there was blood mucus, etc., from the bladder. By rectum, an enlargement of the middle lobe of the prostate the size of a large egg was noted. Calculus was suspected, but no sounding was done because an operation was contemplated in any event. He was admitted January 3, 1903, after pretty thorough preparation at home (he was a private patient).

On January 4 lithotomy and suprapubic prostatectomy without perineal drainage was done by the writer. A soft, porous stone as large as an almond was found encysted in the wall of the bladder in the trigonum. Several smaller stones were also removed. The right, left and middle lobes of the prostate were enucleated. Time, thirty minutes. The portions of the prostate removed were small fibromata, very firm in consistency. (Pathological report by Dr. Mandlebaum.) No shock followed the operation. There was some superficial sloughing of the external wound, perhaps due to the formalin liberated from the urotropin which the patient was taking. He was out of bed five days after the operation. On February 12 the tube was removed and he passed considerable urine, four ounces at a time, by the urethra. February 15 he was discharged cured.

Note.—All edema has disappeared and he can walk six miles at a time without abnormal fatigue. He has remained perfectly well and is apparently rejuvenated.

Case XII.—Hypertrophy of Prostate; Suprapubic Prostatectomy; Cure.

S. S., sixty-five years old, was admitted May 4, 1903. He had been seen by Dr. Wiener in July, 1902, during a similar illness and since then there had been repeated attacks of pain, especially during the past six months. He gave a history of the usual symptoms of prostatic hypertrophy. The prostate was moderately enlarged and tender. No instrument could be passed into the bladder because of an obstruction at the prostatic urethra. Attempts at catheterization had been followed by bleeding. On admission the prostate was found to be, when examined per rectum, moderately enlarged, especially the lateral lobes. The patient passed 3½ ounces of urine, was then catheterized and 22 ounces of residual urine were withdrawn.

On May 17 suprapubic prostatectomy under nitrous oxide gas was performed by Dr. Wiener. Time, seventeen minutes. The prostate, the size of a small lemon, came out in one mass, traversed by the urethra. Convalescence was somewhat interrupted by the formation of an abscess in the scrotum, but about June 15 the patient was passing his urine through the natural channels and was discharged cured.

Case XIII.—Hypertrophy of Prostate; Suprapubic Prostatectomy; Cure.

William N., aged eighty-two years, was admitted January 28, 1903. He had had gonorrhea several years ago, the attack lasting several months. He had had symptoms of prostatic enlargement for many years with his first complete retention about three weeks before, and since then had to be catheterized every day. A soft rubber catheter passed readily. By rectum a fairly hard, medium-sized prostate was felt. On January 28 suprapubic prostatectomy, under nitrous oxide gas and ether, was performed by Dr. Wiener. Time, fourteen minutes. The prostate was two inches in diameter, hard and fibrous, almost globular and traversed by the prostatic urethra. The packings were removed on the third, fourth and fifth days. On February 22 the tube was taken out and a small amount of urine was passed through the penis. After this, except for a slight attack of epididymitis, convalescence was normal and he was discharged on March 24, passing every drop of urine by the urethra and with no residual.

Case XIV.—Prostatic Hypertrophy; Suprapubic Prostatectomy; Cure.

Wolf C., aged fifty seven years, had suffered for about ten months with symptoms referable to

an enlarged prostate. He had had four or five urinations at night, painful and burning. He was admitted on July 3, 1903. One ounce of residual urine was found when catheterized. No. 28 sound passed into the bladder. On July 7 suprapubic prostatectomy was performed under nitrous oxide gas by Dr. Wiener and a mass about the size of a lemon was removed, being shelled out with considerable difficulty in nineteen minutes. On July 17, after good reaction, pyocyaneous infection was found in the lower part of the wound. This infection was killed by the application of ether followed by carbolic acid spray, so that, on the following day, no evidences were visible.

On August 19 the drainage tube was left out of the suprapubic wound, but urination by the natural channels was impossible.

On August 25 perineal section for postoperative stricture of the urethra was performed by Dr. Wiener. Numerous attempts having been made to enter the bladder with a great variety of sounds and catheters without success, a perineal section was made and the urethra opened. It was then found that the deepest portion of the urethra was apparently obliterated. The suprapubic wound was enlarged and retrograde sound admitted with success. Then, when the bladder was inspected with the illuminating endoscope, with the finger in the perineal wound, what appeared to be the urethral dimple could be palpated. The bladder was opened through the perineal incision. Large catheter (30 Fr.) drained through the perineum. The suprapubic and perineal wounds were dressed dry. On September 10 the patient was discharged. He was able to pass every ounce of urine voluntarily, most of the urine coming through the perineal wound but none through the suprapubic opening.

On September 17 the patient was readmitted for the treatment of a right epididymitis which soon yielded to appropriate remedies. The perineal wound had contracted to a considerable degree and it soon healed, but there was constant dribbling of urine, with no voluntary urination. At present he is able to hold six ounces of urine and is gradually regaining normal control, though he finds it necessary to wear a urinal when he goes out.

Case XV.—Prostatic Hypertrophy; Chronic Cystitis; Suprapubic Cystotomy and Prostatectomy; Cure.

M. L. M., aged seventy-five years, had suffered for about five years with the symptoms common in cases of senile hypertrophy of the prostate. He had occasional attacks of epididymitis and was obliged to use the catheter at each urination. For five days before admission on September 5, 1903, he had had daily chills. His general condition was poor although he was quite obese. Slight icterus was present. Emphysema and a slight bronchitis complicated the case still further. His heart's action was irregular and slow, the basal sounds equal and indistinguishable. The first apical sound was rough. The pulse was irregular and of poor quality. On September 15 Dr. Wiener operated under eucaine, 4 per cent., continuing with nitrous oxide gas after the bladder had been reached. The patient's condition being very miserable, the removal of the prostate was deferred for eleven days, until September 26 when it was enulceated in eight minutes with very little hemorrhage under nitrous oxide anesthesia. There were two median lobes the size of a plum. About one inch of the urethra was removed with the prostate. On October 30 he was discharged, still passing his urine through the wound.

Case XVI.—Hypertrophy of Prostate; No Operation; Death.

Charles K., seventy-five years old, was admitted October 25, 1903, in an almost moribund condition, delirious, with urinary sepsis, and two large bedsores. He was not a proper subject for any operation and died on November 4. No autopsy.

Case XVII.—Retention of Urine; Uremia; Prostatic Hypertrophy; No Operation; Death.

I. R., aged ninety-two years, was admitted May 28 almost moribund. His mental condition was such that no satisfactory history could be obtained. His present illness was said to be of two days' standing, during which time he had not been able to urinate without a catheter. Soon after admission 31 ounces of bloody urine were withdrawn with a silver catheter and the bladder was irrigated. Rectal examination showed an enlargement of both lobes of the prostate. On June 7 he died of uremia without operation. No autopsy.

Case XVIII.—Urinary Sepsis; Hypertrophy of Prostate; No Operation; Death.

H. R., seventy-nine years old, was admitted on March 1, 1903. He was mentally and physically incapacitated from giving a clear history. It was ascertained that his illness had lasted about four months, during which time he required constant catheterization. Two days before admission he began to have severe pain in the hypogastrium which became more intense the day before admission. The patient was continually groaning and in a semicomatose condition, with general abdominal pains, most intense in the hypogastrium, and

with a temperature of 100° F., pulse 126 and respirations 30. The man was evidently moribund and it was not considered wise to perform an operation of any kind. He died shortly after admission. Autopsy was refused.

The cause of death in the fatal case of external urethrotomy for stricture is made clear in the following history:

Case XIX.—Surgical Kidney; Stricture of the Urethra; Cystitis; Urinary Sepsis; External Urethratomy and Death.

S. S., a German, aged sixty years, was admitted July 2, 1903. He had had gonorrhea many years before. Four years previous he had had an attack similar to the present one. About three weeks before admission there had been great frequency in urination by day as well as by night. The urine had been red in color and there was great pain during its passage. He was examined on July 4 when it was demonstrated that a No. 11 olivary bougie passed a stricture about four inches from the meatus, but it refused to pass through the entire stricture in the deep urethra. The following day there was a rise of temperature to 102.2° F.

On July 7 a rapid dilatation of the stricture in the penile portion was performed by Dr. Elsberg and an external urethrotomy for the deep stricture. At the end of the operation a 32 Fr. sound was passed into the bladder. The patient reacted well. July 15 the urethra was irrigated through a catheter and sounds up to 31 Fr. were passed. This was done in the morning. At 9 o'clock P.M. there was headache and dizziness and the bladder was found to be distended midway to the umbilicus. Attempts to pass urine voluntarily were ineffectual. A soft rubber catheter passed into the bladder through the perineal wound and 23 ounces of urine were withdrawn. It was of a foul odor, slightly blood-tinged and contained much stringy mucus. The bladder was now irrigated daily through the perineal wound with saline solution. On July 20 the patient urinated partly through the urethra and partly through the perineal wound and two days later there was a chill and a temperature rise to 103° F. From this time on there was a steadily increasing urinary sepsis with chills, rapid pulse and high temperature until August 17, when he died. The blood culture made before death demonstrated the presence of the bacterium coli. Autopsy was refused.

Case XX.—Phagedenic Chancre of Urethra; Incision and Cauterization; Cure.

S. L., thirty-seven years old, married, was admitted October 29, 1903. He had been operated upon for stricture five years before. He said he had had chancre twelve years before and had undergone treatment. There had been numerous attacks of gonorrhea. For two weeks before admission he had noticed swelling of the glans penis accompanied by a slight purulent discharge from the meatus. The discharge showed gonococci. There had been chills and fever. Constant and severe pain in glans penis. On admission it was seen that there was a considerable swelling of the mucous membrane of the urethra, the meatus pouting, an ulcerated area being visible on the roof of the urethra. The glans was glazed and exquisitely tender. A sore was also noted on the left side of the penis in the sulcus behind the glans and there was a painful and enlarged right inguinal gland. He was treated by urethral irrigations and dressings with ichthyol ointment but there was very little improvement.

On November 2, under nitrous oxide gas, the writer incised the urethra from the lower commissure of the meatus for about three-quarters of an inch backward, exposing the large intra-urethral sore. This was thoroughly cauterized with the Paquelin and dressed with iodoform gauze. A perineal urethrotomy for drainage was performed at the same time and a soft rubber catheter sutured in place, so that no urine passed through the urethra. After this there was considerable and rapid improvement and, on November 9 the perineal tube was removed. The wound in the penis seemed to be granulating. The patient passed almost all the urine through the urethra and was out of bed. On November 12, under local anesthesia, about three ounces of thick yellow pus were evacuated from the glands in the right inguinal region, a necrotic gland being, at the same time, withdrawn. The pathological report showed the presence of *Staphylococcus aureus*. About November 16 edema of the penis was practically gone and there was but a slight discharge from the abscess cavity. On November 19 the ulcer had apparently healed and the inguinal wound granulated. There had been for several days an acneform eruption of the face and limbs which was thought to be due to the iodoform. It became fairly characteristic of secondary syphilis, however, and so inunctions were begun. The patient was then discharged from the hospital but has continued under observation. He developed a very acute secondary syphilis and is still under treatment.

operation. This bridge of tissue appeared to have been sewn to a piece of glans which lay below and a considerable distance from the main portion of the glans. On April 14 operation by the writer. The penis was freed by cutting this bridge and the meatus was forcibly dilated to No. 30 Fr. There was considerable improvement and the patient was discharged on May 13, passing a fair stream, and with the organ capable of performing sexual function.

Case XXII.—Double Spermatocele; Excision of One Sac and Incision and Drainage of the Other.

Joseph G., forty-four years old, was admitted April 22, 1903. His history dated back nine or ten years. Both sides of the scrotum were occupied by several fluctuating painless masses, flat on percussion, with no impulse on coughing, and giving all the signs of fluid. The testes were below and behind and slightly tender. The right scrotum was more tense than the left. Each side was about four inches long and three inches in diameter. At operation by the writer on April 25, under nitrous oxide gas, the right sac was excised. On the left side a simple Volkmann operation was performed. The fluid examined at the time showed numerous non-motile spermatozoa. On the right side the spermatocele was in the tunica and the entire parietal portion was removed, the testicle replaced and the scrotum drained. There was no disturbance in healing on this side, but suppuration took place on the other side necessitating a second operation on May 12, when the enormously thickened tunica was removed with prompt recovery. On June 10 the patient was discharged cured.

Case XXIII.—Congenital Inguinal Hernia; Undescended Testis; Bassini and Plastic; Cure.

Louis S., aged thirteen years, was admitted November 11, 1902. He had been kicked in the left groin by a boy two months before. He had always had one inguinal testicle. After the injury a large elastic swelling developed, which was repeatedly tapped but rapidly refilled. On admission the right testicle was normal but the left one was found above the external ring which admitted the tip of the finger. In the scrotum and reaching to the testicle there was a rounded fusiform swelling, fluctuating and dull on percussion. On coughing a mass came out of the external ring which gave the impression that it was connected with the larger mass like the handle of a hammer.

Operation by the writer on November 15 under chloroform anesthesia. The testicle was found in the canal at about the level of the external ring. There was no true hernia, but the testicle acted as a valve shutting off the sac at the external ring. The sac was emptied of its fluid and the epididymis was separated from the testicle along its upper pole and lateral aspect, thus lengthening the cord for a distance of three-quarters of an inch, *i.e.*, lengthening the testicle itself. The remainder of the operation was completed after the Bassini method for the radical cure of an inguinal hernia and the external wound left open. There was some infection, but healing finally occurred by December 13 when the patient was discharged cured.

Case XXIV.—Cystic Sarcoma of Undescended

Testicle; Exploratory Laparotomy and Aspiration of Tumor; Death.

Albert N., forty-three years old, was admitted August 26, 1903. He had had a left inguinal hernia for many years. He had never noticed the presence of more than one testicle. He was married and his wife had had one child. Two years before admission he began to complain of constipation and pain in the lower extremities. He tired easily and, at the same time, he noticed that he was gradually losing weight. He thought he lost at least twenty pounds in one year. Three months before admission he had noticed a mass in the abdomen which he thought had not increased in size and had never been tender. There was no fever or chilly sensations; no jaundice, bowels constipated. The urine had been normal. Lately he had complained of constant pain in the right lower extremity. On examination an enormous mass was found occupying the entire abdomen except the epigastrium and left loin. The mass was felt to be as large as an adult head. It did not move during respiration and it was not tender. It seemed to fluctuate in its upper portion; its lower portion felt hard and nodular. The edge was palpable in the right lumbar region. The tumor was apparently quite movable.

On August 29 an exploratory laparotomy under nitrous oxide gas was performed by Dr. Wiener. The incision was made from the ensiform to the symphysis pubis, exposing the tumor which was apparently a gigantic testicle, epididymis and cord. The growth was as large as a football and the testicular portion was cystic. This was aspirated and about 20 ounces of thick, bloody fluid withdrawn. Enormous veins composed the cord which was intimately adherent to the bladder; this in turn being connected with the testicle by a large gelatinous mass. Posteriorly several large masses of glands could be palpated and the broad pedicle of the tumor could be felt passing backward to the right into the hollow of the sacrum. The case was considered inoperable and the patient's pulse becoming weak the abdomen was quickly closed with through and through sutures of silk. August 31, two days later, he died of exhaustion.

Post-mortem examination was made by Dr. Libman. A considerable amount of blood and fluid was found in the abdomen and, on the left side, a large ring and hernial sac which was reducible. The testicle on the left side was normal. A large tumor (whitish on section) was found in the center of the right half of the abdomen, partly cystic and partly solid. Continuous with it below was a tumor the size of a walnut and from this ran the tube—corresponding to the epididymis—to a triangular pouch resembling a uterus. From the left epididymis the tube ran to the triangular pouch. Both tubes had a lumen which admitted a fine probe and both were attached to the pelvic wall. Below the triangular structure tapered into a canal, which in turn ended in a pouch behind the prostate gland. The ejaculatory ducts communicated with the above pouch. There were no structures behind the bladder corresponding to the seminal vesicles. The kidneys showed chronic interstitial changes, congestion and cloudy swelling. The spleen was large, congested and soft. The adrenals were negative. The liver was cloudy and congested. The entire pelvis was filled by a mass of new growth, white and firm. Veins negative. Microscopically the growth proved to be a round-celled sarcoma.

THE TRACHEAL TRACTION TEST AS AN AID IN THE RECOGNITION OF THE ASTHMATIC LUNG.

BY ALBERT ABRAMS, A.M., M.D.,
OF SAN FRANCISCO, CAL.

THE facts concerning the variation in the percussion note when percussion is executed over the larynx and trachea and certain maneuvers adopted have been firmly established in medical literature. With the widely opened mouth, the percussion sound is louder and becomes increased in intensity; the latter being still further augmented if the tongue is protruded. What is referred to as Wintrich's change of note, is the variation in the pitch of the tympanitic tone, when percussion is executed over the larynx and trachea with open and closed mouth. Opening the mouth raises the pitch of the percussion tone whereas closure of the mouth lowers the pitch.

Baümler observed in many persons that when percussion of the chest is done in the recumbent posture, variation in the pitch of the percussion note remains uninfluenced owing to the fact that the root of the tongue is guided backward, thus more or less completely blocking the entrance into the larynx and in this way interfering with variations in the pitch of the percussion note, the result of opening and closing the mouth. Every act of deglutition lowers the tympanitic percussion sound over the larynx and trachea owing to the fact that in swallowing, the epiglottis covers the laryngeal orifice and narrows it. When the head is thrown forcibly backward, the tympanitic percussion sound is also lowered. Eichhorst[1] attributes the latter change in the percussion note to mechanical causes, assuming that in that posture of the head the vertebral column is arched forward, thus narrowing the pharyngeal space.

That Eichhorst's conception of the cause of the change of the percussion note is undoubtedly wrong, the writer hopes to prove. As far as his knowledge extends, no endeavor has been made to employ the preceding observations practically. Wintrich alone has made a feeble attempt in this direction. He concludes that if, after percussion of the larynx and trachea with open and closed mouth, no change in the percussion note is observable, a nasal obstruction of some kind must exist. The tracheal traction test as employed by the writer consists in percussing the manubrium sterni first with the chin

[1] Physikalische. Untersuchungsmethoden der inneren Krankheiten. 1881, p. 228.

approximating the sternum and then again when the neck is forcibly extended on the sternum. In the former instance, the percussion note is resonant, or even hyperresonant; in the latter posture it is dull or even flat. The alteration in the percussion tone consequent on the foregoing maneuvers is by no means confined to the manubrium sterni but extends to the lung areas on both sides of the latter. While the change already referred to, is not conspicuously palpable to the tyro over the lung contiguous to the manubrium sterni, it is invariably present over the latter area to a degree which is unmistakable.

The writer has for many years employed what he calls the tracheal traction test and finds it invariably present in health, modified of course in intensity by concomitant conditions which also influence other percussion sounds. It is likewise invariably present in all lung affections with the exception of bronchial asthma. In the last named disease, it is not only absent during an attack, but in the interparoxysmal period as well; that is to say, whether the neck is flexed or extended on the sternum, the percussion tone over the manubrium sterni is in no wise influenced but remains the same. The writer is further warranted in concluding from his personal observations that the absence of the tracheal traction test is peculiar to idiopathic bronchial asthma, having found it to be present in symptomatic asthma as in the varieties known as cardiac and uremic asthma. In other words, the tracheal traction test was found to be negative in idiopathic bronchial asthma and positive in asthma of symptomatic genesis. In an affection like emphysema where pulmonary resonance is but slightly influenced, if at all, by both phases of respiration, the tracheal traction test was found to be positive in all the cases examined by the writer. If, in a case of idiopathic asthma improvement is noted, it proceeds commensurately with restoration of the tracheal traction test.

How are we to explain the negative tracheal traction test in asthma? As previously remarked, Eichhorst attributes the change in the percussion note over the trachea when the head is thrown backward to a narrowing of the pharyngeal space by the forward arching of the vertebral column. Insomuch as this narrowing would occur in the asthmatic as well as in the normal subject, we must seek elsewhere for an explanation. Mere traction of the trachea itself cannot explain it for when this structure is removed from the cadaver and percussed after stretching, the percussion tone, instead of being lowered, in reality, raised in pitch. What is lacking in the dead is supplied in the living subject, viz., the tonus of the bronchial musculature. Whatever theory may be adopted in explanation of the asthmatic seizure, we have no reason to doubt the overwhelming evidence in favor of the spasmodic theory, a theory which implicates the bronchial musculature. Even the recent interesting observations of Bullowa and Kaplan[1] do not negative the spasmodic theory. These investigators would have us believe that insomuch as the hypodermic use of adrenalin chloride will abort an asthmatic paroxysm, the angioparetic theory of asthma is favored to the exclusion of the spasmodic theory.

Seven years ago in a paper entitled "A Contribution to the Study of Heretofore Undescribed Neuroses of the Lungs,"[1] I insisted on the necessity of hypothesizing the existence of two distinct functions of the vagus nerve, or the existence of different fibers with two distinct functions: fibers which can dilate (bronchodilator nerves) and fibers which contract (bronchoconstrictor nerves) the lungs upon application of the appropriate stimuli. What I had then deduced as the result of mere clinical observation seems recently to have been conclusively established by the experimental investigations of Dixon and Brodie,[2] which demonstrated that the bronchial muscles are innervated by two sets of fibers, constrictor and dilator sets, both of which run in the vagus. If we have two sets of nerve fibers, we must have two sets of muscular fibers; and that this is reasonably certain is evidenced by the discovery of Aufrecht.[3] The latter asserts that the belief of only a circular layer constituting the musculature of the bronchi is wrong, and that by using the Biondi-Heidenhain stain a longitudinal muscular layer is also found to exist. My discovery of the lung reflex of contraction[4] further supports this belief. The writer contends that the theory of asthma must not alone be based on a spasm of the circular fibers of the bronchi but on an inability of the weaker longitudinal fibers to expel residual air imprisoned by the circular fibers. In employing adrenalin chloride after the manner suggested by Bullowa and Kaplan, the writer, while noting a fugacious abortion of the asthmatic seizures, observed the very pertinent fact that coincident with the dissipation of the paroxysm, the lungs which were formerly hyperresonant became dull on percussion. He then experimented with other agents in the healthy and asthmatic subject and noted that a reliable preparation of ergot, employed hypodermatically, was quite as efficacious as adrenalin and that there was likewise a translation of the percussion sound from resonance to dulness.

There is a preparation largely employed in this country by asthmatics for aborting their attacks which is phenomenally efficacious. The preparation in question is nebulized and while it is supposed to reach the lower air passages, its action is practically confined to the nasal mucosa. Employed after this manner, even in healthy subjects, there is an immediate translation of the normal lung resonance to dulness or flatness; in other words, we induce a veritable lung reflex of contraction discharged through the nasal mucosa just as we can induce the lung reflex of dilatation or the heart reflex through the same medium.

[4] American Medicine, June 3, 1903.

These facts suggest evidence more in favor of the spasmodic than the angioparetic theory of asthma. Four years ago[1] I suggested a method of inhibiting the action of the heart as an aid in diagnosis. For clinical purposes, inhibition of the heart is best attained by voluntary contraction of the muscles of the neck. In some susceptible subjects, mere stretching of the neck suffices to inhibit the movements of the heart, a maneuver which stimulates the vagus, the inhibitory nerve of the heart.

The writer assumes that in applying the tracheal traction test a positive reaction denotes contraction of the bronchial muscle consequent on stimulation of the vagus. We can no longer deny the existence of the bronchial muscle, nor its innervation from the pneumogastric nerve. In the large bronchi and trachea, the muscular coat is well developed and in the trachea its contraction may cause considerable narrowing of the tube owing to the incomplete cartilages. The experiments of Riegel, Edinger and others prove conclusively that the bronchial muscle can be brought to contraction by stimulation of the vagus. In explanation of the dull sound supplanting resonance in the normal subject by tracheal traction, it is reasonable to suppose that owing to contraction of the bronchial muscle, the air in the trachea and bronchi is under considerable tension, the pitch becomes higher and the volume and intensity so decrease that, while percussion formerly yielded resonance, the same act now yields a dull or even flat sound. The negative results obtained in idiopathic asthma in the application of the tracheal traction test warrant the conclusion that in this disease, the tonicity of the bronchial muscle is so reduced that it no longer responds to stimulation of the vagus such as is produced when the head is thrown forcibly backward. The following conclusions may be formulated:

1. When the head is thrown forcibly backward, the normal resonance obtained by percussion over the manubrium and lungs contiguous thereto becomes converted into a dull or flat sound. This maneuver the writer has called the tracheal traction test.

2. The tracheal traction test is positive in health and in all cardiopulmonary affections, but it is negative in cases of idiopathic asthma.

3. The recognition of this test affords a valuable aid in the diagnosis of idiopathic asthma and assists in its differentiation from symptomatic asthma and other spasmodic pulmonary affections which suggest an asthmatic genesis.

4. The maneuver specified as tracheal traction evokes contraction of the bronchial muscle by stimulation of the pneumogastric nerves.

5. In asthma the tone of the bronchial muscle is so reduced that it no longer responds to vagus stimulation brought about when the neck is forcibly extended on the sternum; hence the tracheal traction test in idiopathic asthma is negative.

ACUTE THYROIDISM FOLLOWING CURETTAGE.[1]

BY BROOKS H. WELLS, M.D.,
OF NEW YORK.

SINCE the time when the Roman matron measured with silken ribbon the throat of the bride before and the day after marriage, to determine by its rounded increase that she had been a pure virgin, the sympathetic relation of the thyroid gland to the pelvic organs has been vaguely known; but hardly more than a decade has passed since we began to appreciate the various facts that will in time lead to an accurate knowledge of the functions and physiology of this and the other ductless glands.

Under certain conditions there occurs in those individuals who have been the subjects of a thyroid tachycardia a virulent acute toxemia characterized by a well marked group of symptoms. This toxemia may follow operations upon the thyroid itself, operations upon the pelvic organs, or, more rarely, operations upon the breast or other parts of the body, or any marked nervous strain.

The exact mechanism by which the symptoms are produced or by which the function of the gland is disturbed or excited is not definitely known. The disturbances after operations on the thyroid itself have been attributed to an outpouring of toxic material into the blood, either as the result of the manipulation to which the gland is subjected or from a leakage and absorption from its cut surfaces. These causative factors can be ruled out when the thyroidismus follows operations on other parts of the body. In cases similar to the one recorded below it seems certain that the condition is the result of a reflex disturbance of the central nervous centers and the sympathetic centres that control the activity of the thyroid gland, or, as has recently been suggested, of the parathyroids. The condition is often rapidly fatal, death occurring within the first three or four days from cardiac exhaustion. When recovery ensues the symptoms rapidly or gradually disappear until the individual reaches the status present before the attack.

The following case of acute toxemia with the so-called thyroid symptoms following curettage seems to the writer to posses features of interest which make it worthy of record:

Mrs. X., aged fifty-three years, was referred to me on November 3 by Dr. A. I. Miller, of Brattleboro, Vt. She had passed the menopause at the usual time, but for the last six months had had repeated small bleedings from the uterus, which was not enlarged and was freely movable. The patient was nervous, thin, and poorly nourished. She had had for many years a slight enlargement of the right lobe of the thyroid, an excitable rapid pulse, slight tremor, no protrusion of the eyeballs. Auscultation of the chest revealed a few bronchial râles. No other pathological condition was discovered. To exclude the possibility of beginning cancer of the fundus uteri as a cause

[1] Read before City Hospital Alumni Association.

for the postclimacteric bleeding a curettage of the uterus was advised. This was done at Miss Alston's Sanitarium, with strict asepsis on November 5 at 10 A.M. The scrapings from the endometrium were examined by Dr. Jeffries, pathologist at the Polyclinic, who reported that they showed only a moderate grade of endometritis. There were no further symptoms local or general that could be referred directly to the curettage.

The anesthetic was given by Dr. Bennett and was, as usual, gas followed by ether. After a few breaths of ether the heart became so rapid that Dr. Bennett considered it wise to change to chloroform, under which the heart beats became slower. The time from the beginning of the anesthetic to the return to consciousness was a little less than a half hour.

Six hours later the patient was flushed, tremulous, nervous, voluble, but not worried and with mind clear. The pulse had risen to 130 and became more rapid on any little excitement. Temperature was 100.5° F.

Twenty-four hours after the operation the flush, tremor, nervousness and volubility were increased; the pulse had risen to 178 and was at times uncountable; the temperature was 99.5° F.; there was profuse sweating, a watery diarrhea, marked irritability of the bladder with polyuria, many soft râles all over the chest, and vomiting. The thyroid was perceptibly enlarged, especially on the right side, and presented a quite apparent thrill. There was marked throbbing of the heart and large arteries. Examination of the urine showed a sour odor, reaction neutral, sp. gr. 1,012, no albumin, no casts, innumerable colon bacilli, and a few pus cells. These symptoms of an extreme toxemia continued to the end of the first week, when the temperature reached 101.6° F. and the auscultatory symptoms of bronchitis became more marked, though there was but little cough and expectoration. Blood examination at this time showed no leucocytosis and no typhoid reaction.

On the tenth day the temperature reached 104.8° F. with a pulse of 148. On the eleventh the bronchial symptoms began to subside and in a few days became insignificant.

From the fifteenth to the twenty-fourth day the patient's condition was such that death was expected at any time. The toxic symptoms continued, the tongue became dry and brown, there was extreme weakness, and the usual relation between temperature and pulse was reversed so that the heart action was most rapid and weak when the temperature was lowest.

The diarrhea ceased to be troublesome on the twenty-first day and on the twenty-fourth the patient was able to take small amounts of solid food by mouth. From this time on improvement was steady but slow, until the patient reached a condition approximating that before the operation.

Treatment.—At the beginning it was thought that some of the symptoms might be dependent on an intestinal toxemia and the patient was given calomel followed by a saline and repeated high colonic flushings. The bladder for several days was washed out with a boric acid solution at eight hour intervals, the washing being followed by the injection and retention of two ounces of a 10 per cent. argyrol solution. The diarrhea was finally controlled by tannigen by mouth, gr. x every three to six hours as needed, and starch and decod. tr. opium, m.x. by rectum every six to eight hours. The insomnia was relieved by opium and trional by enema at night, in doses of from xx grs. at first, down to v gr. at a later period. As it became impossible to make the patient retain food given by mouth, rectal alimentation was employed more or less from the eleventh day to the twenty-second. Beef juice and white of egg were the foods best retained and digested by the stomach. Solid food in small amounts was begun on the twenty-fourth day. The heart action and general condition were not benefited by any drug; colonic flushing, strychnine, digitalis, belladonna, suprarenalin, alcohol, all seeming to do more harm than good.

Since writing the above the author has received the reprint of a most interesting paper by Dr. Farquhar Curtis, entitled "Thyroidectomy and Sympathectomy for Exophthalmic Goiter," in which he reports several fatal cases of acute thyroidism and discusses the danger of thyroid poisoning in operations upon persons with exophthalmic goiter. Curtis notes the same symptoms seen in the author's case, the same uselessness of drugs in controlling the excited heart action, and the rarity of recovery when serious symptoms appear. In nearly all of his cases the temperature was high, but with the rise of temperature there was no leucocytosis. In each of the five fatal cases recorded a trace of albumin and granular casts were present in the urine after the onset of the toxemia. In the case noted above there were no traces of albumin or casts until the third week and then a few small hyaline casts and a trace of albumin were present for a few days.

A NEW SLIDE BOX; ALSO A METHOD OF RECORDING EMBEDDED TISSUE.

BY WILLIAM RUSH DUNTON, JR., M.D.,
OF TOWSON, MD.;
ASSISTANT PHYSICIAN SHEPPARD AND ENOCH PRATT HOSPITAL.

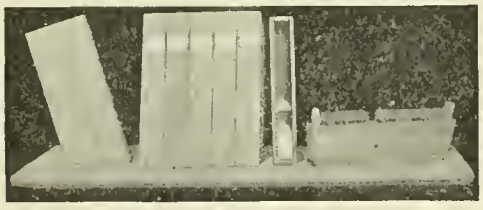
In the *American Journal of the Medical Sciences* for May, 1902, Miss Mary Kirkbride described a slide cabinet, devised by her brother, the late Dr. Thomas S. Kirkbride. Briefly described, it was the application of the card index principle to slide storage, and consisted of a case or shell holding a number of drawers which are made of such size as to hold slides in an upright position when the drawer lies flat on the table, where they can be handled as one does a card index. This shell is inclined at an angle of 75 degrees. The back of each drawer is made at a complementary angle so that the slides lie flat when the drawer is in the case. The advantages of this cabinet are

numerous, chief among them being compactness and the fact that the slides are self-indexed.

After purchasing and using one of these cabinets we were still enthusiastic about them, but had two strong points of criticism, the first being that a number of slides could not be filed as they were too broad, and therefore did not move freely in the drawers. This is a serious drawback as it prevents filing slides in their proper relative position, and when the slide is one of a series the trouble is still more irritating. The other point of criticism is that the cabinets are too expensive. They are most beautifully made, which accounts for the high price ($25) at which they are sold. They are built of 12 drawers, each holding 100 thin slides, so that we pay over two cents storage for each slide in the cabinet. Miss Kirkbride estimates the containing capacity of the cabinet at 1320, which brings the cost below two cents, but even this is an abnormally high price to pay for slide storage. In a laboratory where a certain lot of slides are in constant use the Kirkbride cabinet is most excellent, but as soon as the number of slides becomes large, and they are not in constant use, then the cost becomes excessive.

The principle of the cabinet is so very convenient that Dr. Brush and I experimented to devise a slide box which would preserve the same principle of slide filing, and yet would be about as cheap as the ordinary slide boxes on the market. The result of our experiments has been that we have settled on the box described below.

The boxes are in form essentially similar to the drawers in the Kirkbride cabinet. They are made of one-quarter inch poplar. The outside dimensions are, top 10 1/16 by 1 9/16 inches, the bottom 8 10/16 by 1 9/16 inches, height 4 inches. The lateral view shows a trapezoid, one end being at an angle of 75 degrees. It is on this end that the box rests, when not in use. With lid removed the height of the box is 2½ inches, giving ample room for manipulation of the slides. The lid is



A B C D

A. Shows side view of box. *B*. Shows boxes as they appear when on shelf and not in use. *C*. Shows how slides lie in box when not in use. *D*. Shows box in use. When the box is filled with slides the movable wooden piece is dispensed with.

retained in place by a hook on the "straight" end, the angle at which the inside cleat is placed retaining the other end. The inside width of the box is 1 1/16 inches, giving ample room for slides even when slightly broader than their supposed measurement of one inch. A piece of wood three inches by seven-eighths inch with a brass spring at its side is used to retain the slide in position when the box is not full. Guide cards which stand one-quarter of an inch higher than the slides are used to separate the different groups or series of slides. Each box holds 115 thin slides. A label is placed on the lid and the boxes placed on shelves like books, and a particular box can be readily found and removed without disturbing the others.

To file slides in these boxes it is necessary that a bristol board label be glued upon each end of the slide as described by Miss Kirkbride in the article above quoted. We have found that, if labels of unequal size are used, when the slides are stacked, the curl or warp of the larger label being greater than the smaller one, slides do not lie flat as is desired. We therefore use the same size label on each end of the slide with satisfactory results. These labels are cut from cardboard .5 mm. thick and measures 12 mm. x24 mm. On the upper card is placed the name or case number, the tissue and date; on the lower the staining method or such other memoranda as are desired. In lettering one should remember that the slide stands vertically when the label is read. The cost of these boxes was 16 cents each made in 200 lots. The cost could probably be reduced by two cents if 1,000 were made at one time.

In the first lot of boxes which were made for us a large number had to be rejected, as the maker had not been careful in his measurements and had made them too narrow, so that it was impossible to use them for slides 25 mm. wide, which is the narrowest slide in use. The slides which we have vary from 25 mm. to 26.5 mm. and at least a millimeter should be allowed for free play. Care should be taken to have the boxes made of thoroughly dried wood as shrinking may further narrow the box. One should be careful to avoid falling into the opposite error of making the boxes too wide, as the slides will not lie well if there is too much side play.

For a number of years there has been in use at the laboratory of the Sheppard and Enoch Pratt Hospital a method of recording the tissues embedded for section cutting which has been found to be convenient and practical.

A register of all tissue is kept in a book with vertical columns which are headed according to the various media employed in the method used; and in these columns, on the line devoted to the special piece of tissue in question, is noted the date and time of its being placed in any particular medium. Each method of fixation, also certain special methods of preparing tissue, for example, the Marchi method, is denoted by letter. Tissue from autopsies made at the hospital have the autopsy number prefixed to this letter, and in addition a regular number denoting its sequence in the fixation method. This prefix number is not given to tissues derived from any other source, as that sent in from outside, or from experiments made on animals. The numbers are given consecutively to tissues in the sequence in which they are placed in the fixation methods employed: for

example, A53, and if from a case dying in the hospital, 14A 53, the autopsy number being prefixed.

Other parts of the brain, or other organs, have additional numbers added; for example, the optic chiasm might be 14A 53.1, and the right kidney 14A 53.2. While the kidney or other organs perhaps should have other numbers to differentiate them from nervous tissue, it has been found that it is less complicated that all organs from the one case fixed by the same method should have a common fixation number, and be differentiated by the added number. It may be said in criticism that the autopsy number is sufficient for this purpose; but it must be remembered that a good deal of tissue is handled which does not come from the hospital autopsies, and with these no autopsy or prefixing number is used. The autopsy number serves to more easily identify all tissues belonging to the same case no matter how fixed. It is obviously impossible to give the same fixation number to all tissues belonging to the same case when fixed by different methods as it would make confusion in those methods which are used infrequently.

At autopsies it is our custom to have two large jars containing Zenker's fluid labeled respectively *right* and *left*. Into these are placed the tissues from the organs of the right and left sides of the body, whose character can be easily recognized by inspection. After being taken to the laboratory the contents of each jar are entered in the book, the numbers given in order, and on the first line is noted the time of placing the tissue in solution, ditto marks serving to show the time of fixation of all the other tissues. The jar is then labeled with the tissue numbers and requires no further labeling until the tissues are mounted and the number written on the fiber block, as is the usual custom. Each change of fluid is noted in the appropriate column by the date, and the time when this last is considered necessary. It will thus be seen that we have a very convenient method of keeping record of tissue being prepared for mounting, and this record being permanent we can at once refer to it when any question arises as to the preparation of any section. A glance at the accompanying diagram will perhaps make this a little more clear to the reader. Here a check mark denotes that the tissue has been cut, and a cross, that the block has been thrown away.

" 38.4	Right Kidney etc.	"	"			"	"	"	"	"	"	"	"	

In labeling our slides we use two bristol board labels, one on each end of the slide so that they may be stacked in the boxes described above, On the one is written the tissue number, the name of the tissue, and date of staining. On the other label is placed the name of the staining method, or any other data which we desire to record on the slide. With our system of numbering we are of the opinion that we have a maximum of information with a minimum of writing. Our plan has had a thorough trial and has worked most successfully for a number of years, so that it is now published with the hope that it may prove as useful to others as it has proved to us.

MEDICAL PROGRESS.

SURGERY.

Common Duct Stone and Septic Cholangitis.—While it is generally recognized that jaundice and pain are the commonest and often the only symptoms indicating the presence of a stone in the common bile duct, it is not as well recognized that a certain small number of these cases present, in addition, chills, fever and sweating so characteristically intermittent in character as strongly to suggest a malarial infection. G. E. Brewer (Med. Rec., Feb. 20, 1904) reports three cases of this type illustrative of different degrees of severity. He points out that considerable difference of opinion has existed in the past regarding the etiology of these septic symptoms, some holding that the febrile crises were due to bile absorption through abrasions in the duct mucous membrane produced by the foreign body, while others regarded them as nervous in character and similar to some of the varieties of urethral fever. Most recent observers, however, believe them to be due to septic absorption from infection of the duct, a true infectious cholangitis. Neglected cases coming to autopsy seem to prove this, for the duct is hypertrophied and thickened, the liver the seat of multiple abscesses, and the bile changed in appearance by the presence of pus and blood. The only treatment that can hold out any hope of permanent relief is surgical, choledochotomy, removal of the stones, and hepaticus drainage. The cases reported illustrate how the condition may vary from a scarcely

demonstrable inflammation of the mucous membrane of duct to a chronically thickened wall with surrounding inflammatory tissues, a duct filled with pus, blood and bile, and an enlarged, tender liver. If operation is done early the recovery is usually assured, but if neglected they usually suffer greatly and finally die from a combination of exhaustion, sepsis, and cholemia. In practically all cases the stone is a movable one, and the complete obstruction to the flow of bile to the intestine is due to the swelling of the mucous membrane, evidenced by the fact that bile may be absent from the stools for days after the removal of the stone. This fact emphasizes the necessity of hepaticus drainage in all cases.

Unavoidable External Esophagotomy for the Extraction of a Foreign Body.—The greatest number of foreign bodies that become lodged in the esophagus are either expelled through the mouth or propelled downward into the stomach; this is accomplished either by Nature herself or with the assistance of the surgeon. It is only when it becomes impossible to push the body up or down, for some reason or other, that an external section of the esophagus is called for. BARATYNSKY (Roussky Vrach. No. 12, 1904) reports the case of an insane patient who was admitted with pain in the neck and inability to swallow. According to the nurse the patient had swallowed on the morning of the same day a large stone which the author was unable to dislodge either one way or another. Under chloroform the operator succeeded in extracting through an incision 7 cm. long a stone of roundish irregular form 24 grams by weight. The patient made a complete recovery. The symptoms of this condition are not always clear enough to indicate surgical interference, and Trosseau's sound is often of great value in determining the nature of the body, the depth of where it is lodged and so on. No less important is investigation with the X-rays, which gives good results in the majority of the cases; next to this in diagnosticating the condition is esophagoscopy. In cases where the foreign body has sharp edges or produces considerable hemorrhage immediate esophagotomy is indicated, especially where there are also present inflammatory infiltrations about the neck. As regards the operation itself the anatomy of the parts renders it comparatively easy in early cases. The condition becomes, however, obscure in cases in which inflammatory processes induce considerable disturbance in the anatomical relations of the surrounding structures; the technic of the operation then becomes complicated. The patient may be given liquid food per mouth soon after the operation. The mortality of the operation is variously estimated by various authors and ranges between 20 per cent. and 21 per cent. The earlier the operation the more favorable the result; this, in unfavorable cases, is due chiefly to ulcerations, perforations with attendant purulent foci, hemorrhage, general marasmus, etc.

Chronic Appendicitis.—A discussion on this subject was recently held before the Surgical Society at Paris by GUINARD and LEGARS (Gazz. d. Osped., April 7, 1904) summarizes the following important points: (1) The frequency of unrecognized cases of appendicitis; (2) the frequent coexistence of appendicitis with other diseases of the abdominal organs, when the pain present at the time is almost always of appendicular origin; (3) the necessity for an examination of the appendix in every laparotomy and the extirpation of the same whenever in doubt as to its condition. The authors go even further and extirpate the appendix in every laparotomy that they are called upon to perform. If this procedure, according to them, would have been adopted by them before, they might have saved the life of a woman who succumbed to perforating appendicitis six months after she had been operated on for a uterine fibroma. As regards the frequency of unrecognized cases of appendicitis they report the case of a young girl who had suffered for a long time, and especially so during her menstrual periods, from pains, and in whom there could be detected some tenderness in the right iliac region around the appendicular site. The appendix was found diseased and with its removal the pains ceased. In another girl in whom the pains recurred only during menstruation they disappeared after the extirpation of a diseased appendix. The term appendicalgia should only be applied to cases of appendicular pain in which no organic lesion of the organ can be detected with certainty. In the hysterical there occur painful ovarian areas which simulate very much pains of true appendicitis. It must, however, be remembered that pain is not the principal symptom of appendicitis, for on one hand we do not know the cause of pain in appendicitis, and on the other hand there are many determining factors of pain at McBurney's point. The authors have especially observed this painful area in cases of stercoral typhlitis in whom an evacuation of the intestines causes an immediate disappearance of the painful spot, and they even observed a similar occurrence in a case of pneumonia. They also referred to an appendectomy in the early stage of typhoid fever under the impression that the pain in the right iliac region, complained of by the patient, was referable to a lesion in the appendix.

NEUROLOGY AND PSYCHIATRY.

Are Nervous Diseases Increasing?—Many writers state on apparently the highest authority that nervous diseases, more particularly those of a mental nature, are rampantly increasing. JOHN M. RHODES (Brit. Med. Jour., March 12, 1904) reports that the rise from 87,000 to 116,000 in the number of certified insane is a grave question for all. There are probably two factors which have not been adequately considered in the explanations attempted. The first is that undoubtedly in the last twenty years there has been a marked change in the attitude of the public to the institutional treatment of sick friends and relatives. This has been most thoroughly demonstrated in the case of infectious disease such as tuberculosis, and a glance at the increase in the sanitaria both in Europe and America, show that those families having the burden of insane members upon them have not been any less anxious to accept sanitarium treatment than in the case of patients suffering from infectious diseases. Not alone has this been due to the increased intelligence and the decreased opposition of the layman to the public treatment of his insane, but to the fact that he has been obliged by the segregation movement of the last twenty-five years, to dwell in small quarters in huddled tenements. This factor has probably counted more than any other in stopping the home treatment of the insane and must be considered when interpretation of the records of such towns as London, Manchester, New York and Chicago are undertaken.

Tetany in Colitis and Phthisis.—Tetany and mucomembranous colitis are both somewhat rare and the occurrence of each in a tuberculous case at the same time is interesting. H. H. THOMSON (Brit. Med. Jour., March 12, 1904) gives the history of a young woman aged twenty-one years, who was recently brought into the sanitarium of which he is resident physician. Her condition on admission was good. During the first three months she gained 17 pounds. She gradually began to complain of pain after eating, and constipation became extremely marked. At this moment, a sudden change took place in the disposition of the girl. From being happy and contented, she became irritable and hysterical and tremors gradually developed. The stools

at the time became soft and slimy, were occasionally streaked with blood and developed the typical signs of membranous colitis. The shreds did not ever exceed four inches in length. The temperature had slowly risen, but it scarcely reached 102° F. From this time on she improved and was virtually convalescent, when, suddenly, without warning, after a severe cramp, considerable blood was passed by rectum. Immediately after this flow, she had a severe and characteristic attack of tetany. She was for a time inarticulate. Finally she was able to say: "I cannot open my hands." The thumbs were flexed and pressed tightly into the palms, the fingers flexed at the metacarpophalangeal joints, while extended at the terminal joints. The hands were flexed at the wrists and the arms were crossed on the chest. The feet were arched and extended. The lips were pursed as though attempting to whistle. The face was pale, the extremities cold, the pulse feeble. There were but two severe attacks, the second occurring three hours after the first. The attacks were controlled by hypnotics and after a large amount of mucomembranous material had been passed, the patient gradually recovered. The relationship between a characteristic paroxysm of tetany with a form of colitis, which is now regarded as a neurosis, presents an interesting clinical picture.

Differential Diagnosis of Extra and Intraspinal Tumors.—Very few domains of medicine are beset with such difficulties as the diagnosis of spinal tumors. The proper analysis of the case is often rendered impossible by indolence or clouded intelligence on part of patients. According to V. Malaise (Deutsch. Arch. f. klin. Med., Vol. 80, Nos. 1 and 2) the variety of tumor may give some clue as to its position. Thus, if a carcinoma is diagnosed from metastasis in the periphery or in the internal organs, the tumor is almost always extraspinal. The rule does not hold so strictly for sarcomata, since a few intramedullary tumors of this type have been reported. Syphilitic or tuberculous granulomata may occur in either place, but echinococcus cysts are generally outside of the spine. The presence of albumose in the urine generally speaks for a bone-tumor while in sarcoma, cytodiagnosis of the cerebrospinal fluid may aid. Radiography is of value where the growth is situated in the vertebral column but is unreliable if in the meninges. Intramedullary gliomata are often accompanied by internal hydrocephalus and tumors occurring with spina bifida are generally extraspinal ligomata. There are no symptoms which definitely determine the position, and one must be guided by their succession, duration and time of appearance, with extramedullary neoplasms, the first sign of which is usually pain; with an intraspinal position this is absent at first, unless the location is close to the surface of the spine, near the posterior roots. In the few exceptions to this rule, the pain was different; that is, it did not persist for months and years as the only symptom. Later in the course, spinal tumors may also cause pain, but this is generally situated in the periphery, over a large portion of the body, since due to irritation of intraspinal fibers. The most pain is experienced in tumors of the bone, the least in gliomata of the cord or tumors situated in the anterior portions of the cord. An angular kyphosis will speak for caries or carcinoma of the bone, while a round kyphosis occurs both with extra and intramedullary growths. Another valuable sign of the latter is dissociated anesthesia, such as loss of temperature and pain sense with preservation of tactile and muscle sense. In case of gliosis, this will be homolateral, while, if the result of compression, it will be observed in the opposite limb. Irritation of motor nerves and motor paralysis, especially if a large number of anterior roots are involved in a short time, is more common with extramedullary position. The distribution of symptoms is also of value; thus in meningeal tumors it is generally unilateral, less so in bone tumors and quite exceptionally in spinal growths. Brown-Séquard paralysis is thus seen most often with the first-mentioned variety. Owing to the fact that inflammation and hemorrhage is common within the spine, the course is often not so gradual and progressive as without the spine, and the most unexpected symptoms may appear suddenly during any stage of the disease. Temporary improvement is also seen sometimes, though complete destruction of a sensory nerve by a growth external to the spine, may also tend to alleviate the patient's suffering.

THERAPEUTICS.

The Chlorine Technic.—The acetic chlorine solution has thus far met every demand made upon it. Although planned solely as an aid in obstetrics, Douglas H. Stewart (Am. Jour. of Obst., January, 1904) finds that it has strongly appealed to surgeons. After much thought upon this subject and several thousand culture tests covering more than twenty methods of hand sterilization, the author believes that acetic acid is the very best disinfectant; two teaspoonfuls being combined with four of calcinated lime and one quart of cool (70° F.) sterile water. Five minutes' scrubbing with this after five minutes of mechanical cleansing, has always prevented the growth of streptococci, staphylococci and *Bacillus coli communis*, after the hands were intentionally contaminated with those germs in pure culture. It suffices to say only that in practice it is a good rule to consider the antiseptic power equal to 1-500 corrosive sublimate. Chlorine does not escape from the acetic solution very readily, since the acetic acid and lime form a hypochlorous acid. As this is one of the surest bleachers, antizymotics and antiseptics known, it would be most natural to use it in its own proper form were it not for the unfortunate fact that it can only be preserved on ice or in a refrigerator. All germs on the vulva will be destroyed if the solution be used in half strength. Let the solution dry as it will. About one in 15 cultures will take after the washing. In 18 attempts after three washings one hour apart, all were negative. It is a simple matter to remove the objectionable odor of chlorine by washing the hands with a solution of two tablespoonfuls of acetic acid in water.

New Methods of Phototherapy.—In a recent publication Dreyer, of Copenhagen, reported some interesting experiments in connection with the eosin stains when combined with the Finsen light. He found that the addition of a very small amount of erythrosin to the culture media of bacteria caused a very much greater sensitiveness on their part to the yellow and green rays which were otherwise ineffective. The action may take place through a thick layer of skin and he recommended the injections of sterile solutions of this fluid by the Schleich method in order to render the deeper tissues accessible to the Finsen rays. Neisser and Halberstädter (Deut. med. Woch., Feb. 25, 1904) have lately made some practical experiments with this procedure. They treated 25 cases of lupus, scrofuloderma, tuberculous lymph glands and skin cancer. A solution (0.1 to 1 per cent.) of erythrosin in sterile (85 per cent.) salt solution was injected as deep as the effect was desired. In from two to five hours later the Finsen light was applied for fifteen to twenty minutes or longer in the case of a carcinoma. The authors' experience fully confirm the claims made by Dreyer and with it the Finsen rays may be made to penetrate depths never before reached.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

FOOD SUBSTITUTION.

Dietary substitution, and the pernicious habit of giving "something just as good" for human nature's daily food, seem just now to be peculiarly rampant on both sides of the Atlantic. Our British cousins, however, appear to have gotten the best of us, as their cat transactions are reported to be conducted at London in rather a wholesale manner, while as yet we are still doing a small retail business, with the balance of trade decidedly in their favor.

The attention of the London police was first called to the matter by the proprietor of a boarding house, who applied to a magistrate for a writ of ejectment against an Italian tenant, on the grounds that he killed and ate cats. As it was discovered, however, that the English law does not recognize such gastronomic eccentricities as a sufficient justification for the summary dispossession of a tenant who pays his rent, the matter was taken up, according to the *Post*, by the Society for the Prevention of Cruelty to Animals. For several nights a dozen or more of its most skilful agents have been stalking the Squares of Bloomsbury, where the cat purveyors are reported to be doing their hunting, in the hope of catching them red-handed. Thus far, however, they have not succeeded, as either the wily Italians have let *I dare not* wait upon *I would*—like the poor cat i' the adage, or, as an official of the Society rather naïvely explains, it is "a difficult matter to prove the guilt of men who swallow the evidence of their crimes."

In addition to this, the Society for the Protection of Stray and Homeless Cats, of which Her Grace the Duchess of Bedford is president, has enlisted a large force of amateur detectives in the pursuit, by offering a substantial reward for the arrest and conviction of these ruthless foes of Tom and Tabby; while Russell Square and Guilford Street are filled with an army, built on the Sherlock Holmes plan, the pay of which would be sufficient, as Pope says, to endow a college or a cat.

Up to the present time, however, Her Grace seems to have elicited nothing farther than the statement of an Anglo-Italian authority, that while cats are considered to be a great delicacy in Italy, the State forbids their sale as food and on that account they are furnished as rabbits by the butchers. "They are," he says, "bought as rabbits and eaten as cats, and the proper way to cook them is to roast them in an oven, until brown, with onions, bay leaves and parsley, red wine and herbs. They are not nearly so good when boiled. Nor can English-bred cats be compared with Italian cats. The latter are much better cared for and are fed on the best of milk."

All England is taking part in (the discussion, though London is now the storm center, while in the United States, Pennsylvania seems to be in the area of the greatest depression, for if the expression "cats and dogs" is suggestive of a rainstorm, that of cats and rabbits will prove reminiscent of a cyclone, at least to the inhabitants of Ebensburg. For a boarding-house keeper in the "little Italy" of that quaint old town, finding that his guests were growing weary of risotto and spaghetti, made up his mind to try a change in his bill of fare so as to widen the horizon of his commissariat.

Now the Italian mind is a clear mind, and one that is, in the end, apt to achieve results. Its methods, however, are tortuous rather than direct, which makes it more adaptable to the requirements of diplomacy than to the necessities of hotel keeping. So this Latin boniface, instead of seeking his game in the open market, made a playful wager with his friend, one F. Benson, of Barnsboro, that the latter could not shoot a rab-

bit. No marksman cares to have his skill impugned, so Mr. Benson, having been successfully nagged up to the shooting point, departed, leaving this diplomatist to make the preparations to cook his hare, even though it had not yet been caught. But our modern Machiavelli knew men, if he did not rabbits, and the watched pot was boiling when Benson returned with what he called "a fine large cotton-tail." Not only had the thoughtful nimrod shot the beast, but he had skinned it too, so that the feast was ready at the appointed hour.

As to the enjoyment of the partakers, there can be no question, for they, one and all, declared that it was a dish fit to be set not only before an ordinary every-day kind of a king, but was worthy of even Victor Emmanuel himself. "Viva Garibaldi!" sang the chorus, and there was a sound of revelry by night, interspersed with the twanging of guitars and the strident tones of the street piano. But this is a world of sharp and abrupt contrasts, and there was no gleam of light in the windows of a neighboring house, to show the expectant faces pressed against the darkened panes. For the mice were all that played in that bereaved home, and the missing cat did not come back.

How the substitution was discovered we cannot say. Perhaps the baited hunter, proud of his prowess and the nine lives that had been snuffed out at a single shot, grew boastful and confided to his wife, that he, like care, had killed the cat. Or it may be that he met a bunny in a lonely spot, and having read the recent descriptions of the audacious courage and aggressive ferocity of Brer Rabbit, he feared to tackle him alone. He might miss him, or slightly wound him, and then be at his mercy. For rabbits, they say now, have more courage and less discretion than Mississippi bears.

But, be this as it may, the cat was fairly out the bag, and his poor garlic-tinctured bones were picked over in hot anger by the quondam friends. Benson demanded payment of the bet, and when this was repudiated he took the chances of the Mafia's wrath, by playful but indiscreet allusions to "a d——d Eye-talian cat-meat man." But even if he escapes the vengeance of the Carbonari and the terrors of the evil eye, his dream of future peace is ended. For no one kills a cat unscathed, and his guilty conscience in its troubled sleep will dream "of journeys to St. Ives."

"Let Hercules himself do what he may
The cat will mew—the dog will have his day."

NON-MALIGNANT NEOPLASMS OF THE THYROID GLAND WITH METASTASES.

It may not be quite paradoxical to speak of metastases occurring in cases of non-malignant growths of the thyroid gland, for although the absence of generalization is one of the characters of non-malignant neoplasms, exceptions to this rule are not unknown. Thévenot and Patel (*Gazette des Hôpitaux*, 1901) have shown that myxomata may recur locally and even become generalized, while in his thesis, upheld at Geneva in 1882, Michaloff demonstrated that chondromata might become generalized to such an extent that secondary deposits of the neoplasm were found in the lungs, heart, brain, spleen, etc.

At the present time it would appear as proven that ordinary goiter, a non-malignant growth par excellence, can also give rise to metastases, as pointed out by Patel, in this year's March issue of the *Revue de Chirurgie*. The size and age of the goiter do not appear to have anything to do with the production of metastases; the histological make-up of the tumor governs all. Patel believes that goiters giving rise to metastases are always of the colloid variety and that the secondary deposits are more especially found in the bones and lungs. The bones most usually involved are those of the skull, pelvis or spine, in other words, the flat bones. Of all the viscera, the lungs are most frequently the seat of these metastases, and in 1903 Glockner reported the case of an enormous pulmonary thyroid teratoma at the Obstetrical Society of Leipzig.

One of the most interesting features of goiter giving rise to metastases resides in the fact that generalization of the neoplasm characterizes the entire affection. In those goiters giving rise to metastases there is nothing particularly worthy of note in the tumor itself or in the thyroid gland, because quite frequently the goiter is so small that its presence is unobserved. It is for this reason that in all the reported cases it is stated that the thyroid gland appeared normal or that the organ presented signs of ordinary goiter. Carcinomatous transformation of the gland has never been observed in the case under consideration.

There consequently is nothing which would indicate that a goiter will give rise to metastases; and on the other hand, when metastases occur there is nothing characteristic in them. Metastases of the bones of the skull give rise to attenuated symptoms of cerebral compression while those of the vertebræ produce incomplete para-

plegia and neuralgia of the limbs. Metastases in the lungs do not produce any symptoms apparently, so that it can readily be seen that secondary deposits from a non-malignant goiter are rarely discovered until the case comes to necropsy.

The idea that a non-malignant neoplasm may become generalized is so paradoxical that in spite of the recorded cases, one has questioned whether the starting point of the metastases was not to be found elsewhere than in a non-malignant growth of the thyroid gland. Housell believes that the origin of the metastases is to be found in the parathyroids but this opinion seems to be rejected at the present time, while Eberth and Wolfler have contended that the so-called non-malignant goiter was in reality an unrecognized malignant neoplasm of the gland. This opinion does not appear to have gained much support because the histological study of goiters with metastases has never demonstrated the presence of epithelial nests which are characteristic of carcinoma and has simply given the picture of a normal thyroid or one having undergone colloid degeneration. Consequently one has been led to believe that a non-malignant goiter may give rise directly to distant secondary deposits.

The prognosis of metastatic goiter is not easy to decide for the simple reason that the process is only discovered at necropsy, but an interesting fact placed in evidence by Patel is that thyroid grafts never produce the phenomena of hyperthyroidization, but rather to a kind of general cachexia.

The rare instances of this disease in which either medical or surgical treatment has been resorted to would seem hardly to encourage active therapeutics. Jäger tried thyroid opotherapy without success, while Feurer undertook the removal of a metastatic focus of the skull and was obliged to penetrate into the cerebral lobe on account of the extension of the secondary deposit into the brain substance. As to surgical interference undertaken in other regions than the cranium, it would appear that the patients derived little benefit from them.

ECHOES AND NEWS.

NEW YORK.

Sloane Maternity Hospital Appointments.—Dr. Ralph Waldo Lobenstine has resigned from the position of Resident Obstetrician at the Sloane Maternity Hospital. His resignation takes effect the first of September. He has held the position for the last two years and leaves in order to do private work in obstetrics and gynecology. Dr. Lobenstine's successor will be Dr. George Ryder, ex-House Gynecologist at the Roosevelt Hospital.

Experimental Surgery at Columbia.—Dr. J. W. Draper Maury has received a grant of $400 from the Rockefeller Institute for Medical Research. He will conduct experimental work in the subject of Tetany at the Surgical Laboratory of Columbia University next winter.

French Hospital.—The new French hospital on Thirty-fourth Street will be formally opened during the first part of October. It will be twice the size of the present building and will require an increase in the house staff. This has been provided for in the appointment of Doctors C. W. Walser, Henry A. Craige and Wm. Lamb.

Obstetrics at Dartmouth.—Dr. J. O. Polak, of Brooklyn, has been appointed to the Chair of Obstetrics in Dartmouth Medical College made vacant by the death of Prof. W. H. Parish, of Philadelphia.

Coroners' Physicians.—The Board of Coroners met in monthly session last week to consider the apportionment of the work of the coroners' physicians, a rearrangement being necessary owing to the transfer of Dr. Higgins to the position of police surgeon. At the close of the meeting, Coroner Scholer said there was no eligible list from which another physician could be selected. President McCooey, of the Municipal Civil Service Commission, says, however, that the board is prepared to furnish an eligible list of police surgeons from which a coroners' physician may be selected. The Board of Coroners object to this list, saying it is four years old, and claiming that the eligibles may not be pathologists. Referring to the matter, Coroner Goldenkranz said: "Coroners' physicians deal with medical and surgical cases, like the police surgeons, but in addition the coroners' physicians must be learned in the science of discovering abnormal conditions that exist in bodies after death, matters which police surgeons are not called upon to know."

PHILADELPHIA.

Bequests to Hospitals.—Many of the hospitals of the city received bequests of $5,000 to $10,000 from the estate of John L. Devereux, who left $141,000 to charity.

Physical Tests for Teachers.—The Board of Education has passed a by-law requiring all persons seeking positions as teachers in the public schools to undergo a physicial examination. Applicants for admission to the Normal School or the School of Pedagogy must also pass such an examination.

Meat Dealer Fined.—One of the eleven firms charged by Food Commissioner Warren with selling meat preserved with sulphites and other similar substances has been fined $50 and costs; the others have been held for trial.

University of Pennsylvania.—At the one hundred and forty-eighth annual commencement held June 15, degrees were conferred up 650 graduates. Of these, 96 were in medicine, 120 in dental surgery, and 28 in veterinary surgery. The honorary degree of Doctor of Science was conferred upon Drs. George Dock, of the University of Michigan, and Russell H. Chittenden, of Yale; Doctor of Laws on Drs. H. C. Wood, of the University, and H. P. Bowditch, of Harvard, and Sir Frederick Treves, of London.

Jefferson Hospital.—Dr. L. H. McKinnie has been appointed Chief Resident Physician. Dr. W. F. Manges has been made Skiagraphist to the hospital. Changes in the plans of the new hospital have necessitated the removal of parts of the framework erected

last year. When this is done the building will be pushed to completion.

Children's Homeopathic Hospital.—The new wing containing 58 beds has been opened, increasing the capacity of the institution to 130 patients. A recent improvement is an isolation ward where mildly infectious cases can be treated.

Special Lectures for the County Medical Society.—At the meeting of May 25, Dr. J. Madison Taylor read a paper on this subject in which he expressed the doubt that one-half of the members of the Society gather much assimilable knowledge from the ordinary journal article or paper read before the Society. They are not primarily designed to instruct though they may contain admirable facts, formulations and conclusions. They are written for publication and lack the simplicity and directness needed for purposes of instruction. To overcome these disadvantages, Dr. Taylor recommended the establishment of a course of postgraduate lectures by the Society for its own members. Publication in the transactions is not a part of the idea, this giving the speaker more freedom in his explanations and illustrations. The presence of the Secretary of the Society would not be needed at these meetings; discussion on the lectures should not be allowed, neither their publication in the daily papers. Acting on this suggestion, the directors of the Society have recommended a resolution setting apart the third Wednesday evenings of November and December of the present year for lectures on subjects of practical interest.

CHICAGO.

Hospital Dedicated.—The addition to St. Francis' Hospital, Freeport, Illinois, erected at a cost of $47,000, was dedicated June 8.

Appointment of Dr. Dugan.—Dr. Richard D. Dugan has been appointed President of the Illinois Board of Health.

Degree Conferred on Dr. Quine.—At the commencement exercises of the University of Illinois, June 8, the degree of Doctor of Laws was conferred on Dr. Wm. E. Quine.

CANADA.

Perpetuating a Medical Charter.—An interesting ceremony took place one day last week in Toronto when, in accordance with an Act passed at the recent session of the Ontario Legislature authorizing the Government to purchase the building of the old Toronto School of Medicine, the charter was surrendered and perpetuated. An order in council was put through taking over the building at the price of $12,000 as well as the charter of the school. There can now be no revival of that school as a rival to the University. The old Toronto School of Medicine was established in 1851 and incorporated by special Act of the Ontario Legislature, the charter being granted to Dr. John Rolph, Dr. Joseph Workman, Dr. W. T. Aikins, Dr. James L. Gavin, Dr. Russell and Dr. T. D. Morrison. The corporation at the time of its merger was as follows: Dr. James H. Richardson, Dr. Uzziel Ogden, Dr. James Thorburn, Dr. W. W. Ogden, Dr. Moses Aikins, Dr. R. A. Reeve and Dr. William Oldright. Although all of these latter are alive, only the two latter, Dr. Reeve, who is Dean of the Medical Faculty, and Dr. Oldright, who is professor of Hygiene, are in active teaching. The nominal members of the corporation now are: The Hon. Richard Harcourt, Minister of Education; Mr. J. R. Cartwright, K.C., deputy attorney-general; Mr. John Millar, Deputy Minister of Education; Mr. Thomas Mulvey, K.C., Deputy Provincial Secretary, and Dr. C. A. Hodgetts, Secretary of the Provincial Board of Health. The charter of Trinity Medical College was surrendered to Trinity University over a year ago, and in the federation was absorbed by the University of Toronto.

Help for Consumptive Poor.—During the past week there was held in Toronto a meeting of the Executive Committee of the National Sanitarium Association. A check was received from the Hamilton Branch of the Association for $3,000, a contribution from the people of Hamilton and county of Wentworth toward the support of the consumptive poor of those municipalities, at the Muskoka Free Hospital for Consumptives. A pavilion with accommodation for ten patients has been set aside to be known as the "Hamilton and Wentworth County Pavilion," which will be for male patients alone, the female patients being cared for in a ward in the main building. Word was received also that a branch had been successfully established at Ottawa and that some $2,000 had been subscribed, and special accommodation is to be set aside for patients from Ottawa. The Manufacturer's Life Assurance Company also contributed a sum of $500 toward endowing two beds for one year.

Ontario Medical Association.—The twenty-fourth annual meeting of the Ontario Medical Association opened in the Toronto University Building, Toronto, on June 14, and continued in session for the two following days. Dr. James F. W. Ross, the President of the Association, occupied the chair, while Dr. Chas. P. Lusk, Toronto, acted as General Secretary. There was a large attendance of physicians from different parts of the Province, and the meeting was one of the most successful in the history of the Association. The program was a very attractive one, each paper eliciting keen discussions. Among these was one by Dr. H. P. H. Galloway, of Toronto, giving the report of a case of bilateral congenital dislocations of the hips treated by the Lorenz bloodless method, together with a brief review of the status of the Lorenz method. Dr. Ross delivered the annual presidential address. Some of the matters referred to in his address were as follows: "The regular who adopted the methods of the quack was more dangerous than the quack himself; some surgical procedures of the present day require severe criticism; surgeons may be too conservative or not conservative enough; a few years ago we had an epidemic of the former and now we are suffering from a plague of the latter. Referring to the registration of births and deaths and notifying of infectious diseases, they were in doing this work assisting and defending the commonwealth, and the commonwealth should pay for it accordingly. He advocated the establishment by the Association of a special committee to deal with these matters as well as that of commissions to report at the next annual meeting. A symposium on life assurance was the feature of the meeting and occupied the whole morning session of the second day. This was contributed to by well-known medical men in the profession in Ontario, most of whom were connected with life assurance companies as medical directors. The discussion which followed was an animated one and it was quite apparent that the general consensus of opinion was that the fees for examinations were not commensurate with the work performed. One speaker mentioned the fact that in Toronto examinations were done for one company at the rate of 25 cents each, an announcement which elicited nothing but disgust.

At the annual Association luncheon, the Premier of the Province of Ontario was present and delivered an address in which he foreshadowed Government aid to a hospital which is now being considered in connection with the Medical Department of the University. The following were the officers elected for the ensuing year: President, Dr. William Burt, Paris, Ont.; First Vice-President, Dr. John L. Davison, Toronto; Second, Dr. George Hodge, London; Third, Dr. Edward Ryan, Kingston; Fourth, Dr. T. H. Middleboro, Owen Sound; General Secretary, Dr. Chas. P. Lusk, Toronto; Assistant Secretary, Dr. Samuel Johnston, Toronto; Treasurer, Dr. Fred. Fenton, Toronto.

GENERAL.

Association of American Medical Colleges.—The fifteenth annual meeting of the association was held in Atlantic City, N. J., June 6, 1904. Fifty-two colleges were represented. Four colleges applied for membership and were accepted. The application of one college was not acted upon, pending further investigation. The total membership of the association is seventy colleges. The association acted favorably on the recommendation of the Special Committee to continue the visitation and inspection of all the colleges that are members, and the following committees were appointed to report at the next meeting: Committee on Uniform Curriculum: Geo. M. Kober, W. J. Means and Parks Ritchie. Committee on Medical Education: Fred. C. Zapffe. This committee to confer with similar committees from the American Medical Association, Southern Medical College Association, American Confederation of Reciprocating Examining and Licensing Medical Boards, The National Confederation of Licensing and Examining Boards, The American Institute of Homeopatny, The National Association of Eclectic Physicians and Surgeons, and the Association of Physio-medical Physicians and Surgeons. This committee is to consider the question of medical education in all its phases, including preliminary education and entrance requirements. Papers were read by Wm. H. Wathen, Louisville; H. L. Taylor, Albany, N. Y.; Geo. M. Kober and Seneca Egbert, Philadelphia. The following officers were elected for the ensuing year: President, Samuel C. James, Kansas City, Mo.; First Vice-President, R. Dorsey Coale, Washington, D. C.; Second Vice-President, R. H. Whitehead, Chapel Hills, N. C.; Secretary-Treasurer, Fred. C. Zapffe, 1764 Lexington Street, Chicago; Judicial Council, Wm. J. Means, Columbus, Chairma; Randolph Winslow, Baltimore; H. B. Ward, Lincoln, Neb.; Geo. M. Kober, Washington, D. C.; Thos. H. Hawkins, Denver, Colo.; Parks Ritchie, St. Paul, Minn.; John M. Dodson, Chicago. Time and place of next meeting, June 5, 1905, Portland, Ore.

American Gastro-enterological Association.—This Association held its annual meeting at Atlantic City, June 6 and 7. A symposium on Gastric Ulcer was the chief topic of the proceedings. Harlow Brooks, of New York, discussed the pathologic anatomy, and W. G. MacCallum, of Baltimore, the pathogenesis. Campbell Howard (from Osler's clinic) analyzed the postmortem and clinical statistics of many hospitals in the United States and Canada. Symptomatology, course, complications, sequelæ and differential diagnosis were discussed by M. Einhorn, J. Kaufmann, M. Manges, all from New York, and H. W. Bettmann, Cincinnati. Medical and surgical treatment were discussed by S. W. Lambert and J. A. Blake, both of New York; the condition of the blood and urine was discussed by T. Futcher, of Baltimore, and the occurrence of gastric ulcer in children by E. G. Cutler, Boston. Other papers were read by J. C. Hemmeter, J. Friedenwald, both of Baltimore, C. D. Aaron, of Detroit, F. H. Murdoch, of Pittsburg, and F. B. Turck, of Chicago. The following officers were elected for the coming year: President, S. J. Meltzer, of New York; First Vice-President, F. H. Murdoch, Pittsburg; Second Vice-President, H. W. Bettmann, of Cincinnati; Secretary, C. D. Aaron, Detroit; and on the Council, W. G. Morgan, of Washington. The next meeting will take place in New York during the Easter vacation.

Tulane University.—By the will of the late A. C. Hutchinson of New Orleans, Tulane University of that city will receive cash and personal property worth nearly $800,000 as an addition to its endowment.

Inter-State Indorsement vs. Inter-State Reciprocity in Medical Licenses.—The following resolutions were introduced by Dr. E. L. B. Godfrey, secretary State Board of Medical Examiners of New Jersey, at the meeting of the Confederation of State Medical Examining and Licensing Boards, Atlantic City, N. J., June 6, 1904:

WHEREAS, national legislation cannot affect the question of State jurisdiction in medical practice without the surrender of definite State sovereignty, and

Whereas, State medical examination is the basis for State medical license, or the indorsement of a license issued after an approved examination of another State, and each State is the judge of the qualifications of its medical licentiates, and

Whereas, it is manifestly unjust and a cause of open complaint by the profession to compel an experienced physician, licensed after State examination, to undergo a second examination (practically a re-examination in the same elementary branches) upon removing from one State to another, when the requirements for medical license in the two States are substantially the same, or lower in the State from which indorsement is asked; therefore

RESOLVED: That it is the sense of this Confederation that, among those States whose standards of requirements are equal or substantially the same, their licentiates by examination who can meet the moral, academic, medical and examining requirements of the State whose indorsement is asked, are entitled to and should be indorsed, irrespective of reciprocity.

Resolved: That when the standard of requirements of any two States are unequal, it is in the interest of the profession that the State having the lower requirements should indorse the examined licentiates of the State having the higher requirements, irrespective of reciprocity, when such candidates can meet every legal and educational requirement of the indorsing State.

Resolved: That reciprocity limited by statute to reciprocating States, which demands equal rights and privileges in return as conditions of indorsement, with the purpose of compelling recognition of its own licentiates, is detrimental to and retards the progress of the profession, because: (1) It restricts the extension of indorsement by its limitations. (2) It causes hardship to the profession because of its uncertain tenure. (3) It excludes indorsement from States having higher requirements by reason of which reciprocity cannot be effected. (4) It refuses recognition to distinguished physicians of non-reciprocating States. (5) It recognizes neither the merit of a State examination nor that of the licentiate as compared with reciprocity. (6) It tends to maintain standards at the level of the lowest reciprocating State, and offers no inducement for a State to raise its

standards above those of its reciprocating neighbors. (7) It practically involves an omnibus indorsement, without inquiry as to the status of the individual candidate, and without discrimination, since all licentiates of a State stand legally upon an equal footing. (8) It is impractical for adoption by any considerable number of States, because of the difference in State laws, standards and population.

Resolved: That reciprocity based upon a voluntary agreement of State boards is, like statutory reciprocity, impractical, because: (1) There is no uniformity in State laws and no ability to enforce them. (2) When differences arise between Examining Boards, in respect to the status of colleges, the grade of examinations or the eligibility of candidates rejected by one Board for examination by another, there is no law, national, interstate, or state, to adjust the differences or to enforce the agreement which may be broken at the pleasure of either Board and without redress.

Resolved: That inter-state indorsement, authorized by statute and exercised at the discretion of a State Medical Licensing Board, irrespective of reciprocity, based upon the substantial equality of educational requirements, upon a State examination satisfactory and approved as to kind and grade, and upon the individual merit and the professional qualification of the candidate for indorsement, is far better than indorsement based upon either statutory or voluntary reciprocity, and tends more than either to further the cause of higher medical education and the autonomy of the profession throughout the country. (1) It is good State policy since it neither denies citizenship nor the right to practice to any physician entitled through merit to its privileges. (2) It makes the State the sole judge of the qualifications of its licentiates by enforcing the same requirements for indorsement as for examination for license, thus placing all licentiates on the same footing. (3) It accepts a State examination for what it represents as an examination, but not as more important than the merits and qualifications of the candidates for indorsement. (4) It tends to raise and maintain a high standard of education by making a license from a State with high requirements more widely acceptable for indorsement than one from a State of low requirements, and thus admits of early national application. (5) It requires legal evidence of individual merit as well as professional qualifications for approval for indorsement, and thus tends to reduce to a minimum the indorsement of irregular, itinerant practitioners. (6) It puts a premium on character and education and renders the best practitioners eligible for indorsement in every State. (7) It indorses both the State and the individual candidate, and failure of a State to reciprocate, therefore, does not afford either a legal or valid reason for rejecting any of its licentiates who can meet every requirement of the statute. (8) It may accept any of the examined licentiates of a State for indorsement, or only those examined and licensed under the most recent requirements.

Resolved: That a State that will not indorse the examined licentiate of another State where the standards are co-equal, or of a State where the standards are higher, stands as a hindrance to medical progress, because: (1) It does not recognize the efficiency once proved by examination in a State of co-equal or higher requirements. (2) It limits the working sphere of the profession. (3) It exacts the same requirements for license from the physician, duly licensed after an examination in a co-equal State and experienced by years of practice, that are exacted from the inexperienced graduate.

Resolved: That indorsement, therefore, irrespective of reciprocity, should be granted to examined licentiates of States whose standards of requirements are co-equal or higher, when the candidate for indorsement can meet in all respects the requirements of the statute governing the practice of medicine.

After discussion, the resolutions were ordered to lie on the table, to be printed by the Secretary, distributed among the members and presented for consideration at the next meeting.

OBITUARY.

Dr. D. J. Treacy, one of the best known practitioners in the southern section of Philadelphia, was found dead in bed on June 20. Heart disease, from which he had suffered for some years, was the cause of death. Dr. Treacy was born in Ireland but came to this country in boyhood. He was sixty years of age. He graduated at Jefferson in 1867.

Dr. James Simpson, sixty-five years old, and a practising physician on Pine Street, Philadelphia, for a quarter of a century, died June 20 from an illness beginning in March; an operation three weeks ago failed to improve his condition. During the Civil War he was appointed a surgeon and had charge of the hospital corps at Alexandria the entire time, although he had not yet finished the course at Jefferson.

Dr. Nathan Smith Davis, Sr., died at his home in Chicago, Ill., Thursday, June 16. He was eighty-eight years old. He was born Jan. 19, 1817. He was one of the founders of the American Medical Association; also one of the founders of Northwestern University, the Chicago Academy of Sciences, the Chicago Historical Society, the Illinois State Microscopical Society, the Union College of Law, and the Washingtonian Home for Inebriates. His fame as a physician was by no means confined to the boundaries of Illinois, for he bore an exalted reputation in his profession throughout the entire country. In 1855 he became editor of the *Chicago Medical Journal.* In January of 1860 he started a new magazine, and called it the *Chicago Medical Examiner,* which he continued as an independent journal until 1873, when both publications were merged under the title of the *Chicago Medical Journal and Examiner.* In 1883 he was chosen editor of the *Journal of the American Medical Association.* The most important of Dr. Davis' writings is said to be a text-book on agricultural chemistry, used in district and public schools. He was also the author of a history of medical education and institutions in the United States from the settlement of the British Provinces to 1850. He was a frequent contributor to the current periodical medical literature.

Dr. James H. Dunn, of Minneapolis, Minn., after reading a paper before the American Surgical Society at St. Louis dropped dead in his room June 16. He was forty-eight years old.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, held at Atlantic City, N. J., June 7 to 10, 1904.

SECTION ON MEDICINE.

Third Day—June 9th (*Continued*).

(Continued from Page 1189.)

Microbic Infection.—The discussion was opened by Dr. Anders, of Philadelphia, who said that while microbes are a necessary element in the causation of gallstones an additional factor is required. Local congestion in the biliary tract and the inspissation of bile, with consequent lack of drainage invite infection. It is important then that the gastro-intestinal tract should be

kept in the best possible condition so as to avoid these local disturbances in the biliary tract. The part of the medical man is as far as possible to prevent the formation of gall-stones and remove the causative conditions. It is interesting to have Dr. Sippy say that medical measures, rest and diet may overcome the tendency to contraction of the pylorus which sometimes occurs in connection with gall-stones and which makes the patient so unsuitable for the serious operation. In this matter of preparation for the operation, the medical man can be of great use to the surgeon. In Dr. Anders' experience, just before the occurrence of true gall-stone colic, there is pain referred to the tenth dorsal vertebra. This pain is not found in cholecystitis. The latter is accompanied rather by a sense of vague discomfort than the boring pain referred to the lower dorsal space. Early diagnosis is important, between these conditions, for while cholecystitis is a medical affection, cholelithiasis must not be given over to the surgeon.

Gall-stone a Foreign Body.—Dr. William M. Mayo, of Rochester, Minn., said that the touchstone of cholelithiasis as a surgical condition is the fact that a gall-stone is a foreign body and must be considered as such. Whenever it gives trouble it should be removed. Many gall-stones slumber for long periods, even for a lifetime, but, as a rule, once they awaken they do not slumber again. At the present time the mortality from operation for gall-stones in uncomplicated cases is not more than three per cent. Even this is largely accidental. Operation is not much more dangerous than for appendicitis in the interval. The trouble is that cases go too far before being referred to the surgeon. It is proper for the physician to state deliberately to the patient how much of added danger delay will bring. The mortality in complicated cases is 16 per cent. in the most experienced hands. If this is explained to patients, there will be less likelihood of their putting off the operation too long.

Benefits of Operation.—After the removal of gall-stones other chronic conditions in the gastro-intestinal tract, and especially in the pancreas, subside. The chronic inflammation of the pancreas, which may become serious, disappears on proper drainage of the biliary tract. Dr. Mayo has found on several occasions that the blocking of the duct of the pancreas has led to an enlargement of the head of the pancreas behind which the common duct became hidden. After drainage of the gall-bladder this became reduced in size and revealed the presence of a stone that had been hidden behind it.

Bile and Pancreatic Fluid.—Dr. William S. Thayer said that he had had the opportunity to read Dr. Opie's paper and that in Dr. Opie's absence he wished to discuss some of the points that would have been presented. Dr. Pavlov, of St. Petersburg, has shown that bile increases the fat-splitting power of the pancreatic juice three to four fold. It does this for all the ferments, but especially for the fat-splitting ferments. Hence, very probably, the reason why the entrance of bile into the pancreatic duct gives rise to acute pancreatitis. Dr. Opie has shown that the existence of even a small stone in the papilla of the common bile duct may lead to the passage of bile into the pancreas. As both the pancreatic and biliary ducts empty through this orifice this is not difficult to understand and he has demonstrated biliary staining of the pancreatic ducts. Gall-stones then are associated with pancreatitis, probably in a causative relation. It has been found that a fat-splitting ferment may be found in the urine whenever there is disturbance of the pancreas. This has been demonstrated on dogs in whom bile was injected into the pancreas. This will probably prove of service in the diagnosis of pancreatic conditions. Whenever at abdominal operations, spots of fat necrosis are found on the peritoneum all gall-stones should be removed. They are probably the cause. Such conditions may develop without extensive pancreatitis and the prognosis is by no means fatal. These small stones, which give rise to such conditions, may or may not cause jaundice, though usually this symptom is present.

Gall-bladder Pain.—This may occur either before or after the taking of food, usually on an empty stomach but, at times, just after taking food, simulating gastric ulcer. Emaciation in connection with gall-stones is usually due to adhesions of the pylorus. These may lead to dilatation of the stomach and the largest dilatations Dr. Thayer has ever seen were due to this cause. In a case seen recently, on the other hand, the pain felt was in the median line and bore no relation to food and there was large dilatation of the stomach. Only a slight superacidity was present, and it was concluded that the condition was due to gall-stones. At operation two ulcers of the stomach, causing blocking of the pylorus, were found.

Early Operation.—Dr. Thayer said that the important matter must be to insist on having early operation for gall-stones. If surgical intervention is delayed it may be found that coagulation time of the blood has increased very much, even up to twelve or fifteen minutes, and as a consequence, after operation the patient bleeds to death in old cases of gall-stones; this is one of the most serious possibilities that have to be faced.

Intrahepatic Stones.—Dr. J. C. Hemmeter, of Baltimore, said that in a recent case under observation, the patient, the wife of a physician, had suffered from typical symptoms of gall-stones and a resection of the gall-bladder was done. A number of stones were found and removed. After the operation, however, the symptoms redeveloped and a second operation had to be done, when three stones were found in the gall-ducts within the liver. This emphasizes the necessity for careful searching for gall-stones in these cases in order to avoid the necessity of a repetition of the operation.

Gall-stones and Metabolism.—Dr. Hemmeter considers that certain disturbances of metabolism are constantly associated with the formation of gall-stones. Overeating, and especially the overconsumption of fats, is one source of this metabolic disturbance. In those who have given any signs of discomfort in the biliary region it may be important to try to do away with gastro-intestinal disturbances of every kind. The differential diagnosis of gastric ulcer and gall-stones remains a very difficult matter. It must be remembered, however, that in gastric ulcer a peptic ferment occurs in the urine and the finding of this may be one element in the diagnosis. On the other hand, orthoform will prevent the pain of ulcer if administered before the giving of food and will stop the pain after it has begun by its local action upon the tissues. Orthoform will not, of course, affect cholelithiasis.

Cholelithiasis, Surgical not Medical.—Dr. Frank Billings, of Chicago, said that there is no medicine and no system of remedial measures that will dissolve a gall-stone once formed. As has been said, a gall-stone is a foreign body, and if it is giving symptoms, should be removed. Drainage of the gall-bladder by preventing the progress of infection may save recurrence of painful conditions. Internal drainage by means of cathartics, may accomplish this same purpose. Hence the benefit derived by the treatment at Carlsbad. Once the gall-bladder has become infected, however, the case should be handed over to the surgeon. A single attack of gall-stone colic is not enough to justify this, but if attacks have been repeated, especially at brief intervals,

then there seems no hope of relief by the passage of stones.

Toxin and Pressure.—Dr. Wilson said, in closing the discussion, that some of the cases are overwhelmingly toxic, due to pressure. All the cases in which he has seen lumbar puncture followed by the exit of bloody fluid from the spinal cord have been unfavorable. On the other hand, when the fluid is clear the prognosis is favorable. This is the experience also of Dr. Riessman, who has had three fatal cases in which bloody fluid was present. With regard to failures to obtain fluid on lumbar puncture, Dr. Wilson considers that too short a needle is generally responsible for this. A four-inch needle is sometimes recommended. Dr. Wilson has used a five-inch trocar and canula and never fails to get in or to get fluid.

Amebic Dysentery.—Dr. James P. Tuttle, of New York, said that when the Shiga bacillus was discovered it was considered that most cases of dysentery were due to this. The *Amœba coli*, however, had been previously shown to occur in certain cases. Now, it is known that there is a third type due neither to the ameba nor to Shiga's bacillus, nor so far as is known to any specific microorganism. Dr. Tuttle has had the opportunity to study 74 cases of amebic dysentery in which motile amebæ were found in the stools or the scrapings of the ulcers. In these cases the symptoms disappeared with the ameba and recurred when it could be found again. The source of the ameba is not known. It differs from the fresh water ameba by its susceptibility to changes of temperature. Fresh water amebæ are motile at high and low temperatures. Dysenteric amebæ are killed by a reduction of temperature. The size is not enough for the diagnosis. It used to be considered that these microorganisms increased by division. Now it is thought that they increase rather by sporulation.

Low Temperatures Unfavorable.—The life of the ameba at human temperature seems to be indefinite. Whenever the temperature is reduced to 70 degrees, however, the motility of the organism disappears and does not reawaken. Cold is much more effective than any chemical agent in producing death. In order to examine the stools for ameba, the feces must be obtained warm. They must also be examined upon a warm slide. One of the easiest ways to find them is from the scrapings from ulcers as obtained through a proctoscope.

Dr. Tuttle has found them in long-standing mucous colitis with constipation rather than diarrhea. In a patient now under observation mucous colitis has continued for four years, without any thought of a possible connection with the ameba. Yet these organisms have now been found. It is often said that the ameba has its home principally in the tropics. But they seem to occur almost anywhere. Three of Dr. Tuttle's patients have never been out of Greater New York. Cases are known where patients always lived in New England, or even in Canada.

Ulcerative Lesions.—The ulcers due to the *Amœba coli* are said by Roger and Futcher to occur particularly in the caput coli. Dr. Tuttle has always found them, however, in the rectum and the sphygmoid. Where ulcers occur higher up, the cases are more obstinate to treatment. The amebæ do not occur on the surface of the ulcers but in the submucosa. Here no chemical antiseptic can reach them, hence it is hopeless to expect a cure by means of quinine or other injections. The amebæ will not, however, live at a temperature below 65 degrees. Dr. Tuttle has found that the best treatment is by large injections of ice water. The rectum is flushed with ice water with the patient in the knee-chest position and as much water as possible retained.

Surgical Treatment.—In obstinate cases where the disappearance of ulcers in the rectum and sphygmoid is not followed by relief of symptoms and where there is tenderness over the caput coli, Dr. Tuttle suggests the usual incision for appendicitis, the stitching of the appendix into the wound and then, after adhesions had formed, the cutting off of the appendix. Through the opening into the bowels thus afforded cold water is injected by means of a catheter and the affection is relieved. The patient, as a rule, is around in ten days and suffers no inconvenience. Dr. Tuttle exhibited a physician who had been thus treated and who has been cured of an amebic dysentery which had existed four years.

Simulation of Gastric Disease.—Dr. Allen Jones, of Buffalo, said that patients with latent gall-bladder disease, frequently suffer from stomach symptoms. While the characteristic colic occurs usually on an empty stomach, it is not unusual for patients with gall-stones to have discomfort after eating. As the result patients frequently think that they have stomach disease, but chemical examination shows normal secretion and motility. In these cases, however, suspicion with regard to the possibility of gall-bladder disease should be aroused and then sometimes further confirmatory symptoms will be obtained.

Non-surgical Gall-bladder Disease.—Dr. James C. Wilson, of Philadelphia, said that there are two classes of patients suffering from gall-stones who must not be considered surgical. In the first class there is permanent latency of the disease except for vague discomfort, which does not advance beyond this. In the other, after a typical seizure, or even two, of gall-stone colic, a stone is passed and then there are no further symptoms. These are the cases that make physicians hesitate as to the recommendation of surgical intervention. They are, however, very rare and should not be allowed to count for much in the formation of the physician's opinion. It is from these cases too that the traditions with regard to supposed therapeutic efficacy of small doses of chloroform or of large doses of olive oil are derived. Gall-stone disease, however, in the great majority of cases is a surgical and not a medical affection, and exceptions only serve to illustrate the rule.

Ergot in General Practice.—Dr. Alfred T. Livingstone, of Jamestown, N. Y., said that ergot has unfortunately been used only in one branch of medicine while undoubtedly the drug has applications in many. He has found it of great service in a number of affections. Wherever there is passive congestion with relaxed unstriped muscular tissue, ergot gives tone and thus affords relief of many symptoms. Not infrequently paresis of the vasomotor nervous system can be relieved by this means. As a rule, the conditions which develop as a consequence of lack of tone in the nervous system are treated by means of stimulants. These do good only for the moment, but eventually always do harm. Strychnine, digitalis and alcohol are unreliable and after a time patients become accustomed to them. In some cases overstimulation may even prove fatal. Stimulation of the heart for instance, inevitably increases weakness, but does not overcome it.

Equilibrium of Circulation.—What ergot especially effects is an equilibrium of the circulation. When the heart is laboring and the unstriped muscular fibers in the blood vessels are relaxed there is no proper response to the heart's work in the elasticity of the arteries. As a consequence circulatory conditions become worse and worse. On the other hand, when the heart is doing excessive work and there is high tension in the arteries, ergot will correct this and bring about circulatory equilibrium much better than can be accomplished by

depressant drugs. In recent years it has come to be realized that shock is a vasomotor paresis of the abdominal blood vessels. It is in this region of the body especially that ergot can be depended upon to give tone to the vessels. It would seem then to be the peculiar province of this drug to correct conditions that lead to shock and collapse. Dr. Livingston's attention to the value of ergot was first called by the benefit derived from its use in insanity. In all forms of functional nervous disease, however, it has a definite value. Pain is usually the result of pressure upon nerves and this pressure is due oftenest to a congestion consequent upon loss of tone in the blood vessels. In these cases ergot often does good. In neuritis, in certain forms of neuralgia, in many cases of angina pectoris and even in such conditions as intestinal colic ergot may be of distinct service. In the nervous symptoms due to alcoholism or to drug addictions no other remedy is so helpful. Morphine may be cut off at once and yet no evil results follow. While ergot is not a narcotic it serves to promote sleep by maintaining a certain anemia of the brain after the intense hyperemia consequent upon drug or alcoholic excesses.

Illustrative Case.—A physician recently under Dr. Livingston's care had been taking two drams of morphine a day and two drams of cocaine a week. As the result of the hypodermic injection of two drams of ergot, he slept quietly for forty-two hours, being awakened at intervals in order to be given liquid food and drink, but dropping off to sleep again at once. No collapse followed, though no further morphine was allowed and no cocaine or any substitute employed. No other hypnotic was thought of and the result has been a complete cure of the case.

Paretic Convulsions.—Dr. Stranahan, of New York, said that ergot is a popular drug in insane institutions and has become the standard remedy for cases of paretic convulsions. At first chloral and ergot were given in combination by the rectum, but ergot alone is really better. Nothing will control these convulsions like this drug. In general practice Dr. Stranahan has found ergot very useful especially in the congestive stage of pneumonias. Sometimes it seems even to abort the disease. In a case recently seen the temperature was above 106° F. and the pulse 135 and the patient delirious. After the injection of two fluid drams of ergot, repeated once at the end of two hours, the temperature fell to 103° F. and the delirium disappeared. In spite of the alarming beginning the pneumonia did not run a severe course.

Postanesthetic Nausea.—Dr. Basch, of New York, has found ergot of good service in reducing the nausea which occurs after anesthesia. The drug is given for several days beforehand and contributes not a little to calm the patient. After its use even when there has been decided manipulation of the inestines, very little shock is noticed. The racking headache so common after anesthesia is very much lessened by its use. There is a popular impression, according to which patients dread the anesthetic more than the operation itself. This is due to the unpleasant after-effects, and these can be greatly lessened by means of ergot, thus encouraging patients to undergo operations for which they would otherwise be unwilling.

Neurotic Conditions.—Dr. James J. Walsh, of New York, said that his own experience with ergot is limited to seeing its effects upon delirious alcoholics, where it undoubtedly is of great service. Dr. Homer Wakefield, of New York, however, who has seen good effects from it in many neurotic conditions, but who is unable to be present at the meeting asks that his opinion of its value for such affections be stated. In the neurasthenic conditions, which are responsible for the tired feeling and which are probably due to relaxed conditions of the abdominal blood vessels with consequent sluggish circulation, ergot is the best remedy and is much better than any of the stimulants that are ordinarily employed. Dr. Wakefield has also found ergot of decided benefit in the treatment of heart disease with lost compensation especially in combination with the Schott method of treatment. He has found that dilated hearts may, after the use of ergot and the consequent lessening of resistance in the circulation, be demonstrated by the X-rays to be smaller in size.

Wet Brains.—Dr. Alexander Lambert, of New York, said that ergot is undoubtedly the best remedy for acute alcoholism that has yet been introduced. In the very severe cases of alcoholic delirium in which there is a tendency to edema of the brain, these cases being usually known as wet brain, no other remedy has been so effective. For the tremor of alcoholism ergot is a rapidly effective remedy. Recently when going on his service at Bellevue, Dr. Lambert found 16 patients who had to be tied in their beds. After the use of ergot all of them could be relased from their bandages and though they continued to mutter in delirium, they were comparatively quiet. Ergot is the only remedy which allows morphine to be taken away at once without inflicting great suffering upon the patient and without the danger of sudden death. Dr. Lambert has never seen a case of collapse after the sudden withdrawal of morphine when ergot was given.

Nauseating by the Mouth.—Dr. Livingston said that the action of ergot is uncertain when given by the mouth, since it often proves very offensive to the stomach and as a consequence of this is absorbed very slowly. When it is needed its action is wanted at once, therefore it is better to introduce the drug hypodermically, when its effect is certain and immediate.

Differential Leucocytosis.—Dr. William Krauss, of Memphis, Tenn., presented some studies in the differential leucocytosis of fevers which had been made with the idea of seeing how far this method could replace culture methods in districts where these cannot readily be obtained. The result is that for tentative diagnosis in the beginning of typhoid fever, or in malarial infection when the parasites are not found at first, a specific picture is obtained. In malaria without much fever, before quinine has been administered, the polynuclear leucocytes are much reduced in number and the large mononuclears are correspondingly increased in size. In cases where there is for any reason a large number of glands enlarged this will not be true. In malarial infection under quinine, the number of polynuclears rises to 80 per cent., though the large mononuclear leucocytes exceed in number the small mononuclears. Typhoid fever may give the same picture as malaria at the beginning, but while waiting for a Widal reaction, the giving of quinine would be justified, since the presence of malaria is much more likely. In gradually developing fever there is an absence of marked increase of large lymphocytes, or of polynuclears, which is characteristic of this type of fever. Accordingly, a suspicion of typhoid would be aroused and precautions could be taken against possible infection, even before a Widal was positive on the strength of this picture.

Uremia and Eclampsia.—Dr. Robert N. Willson, of Philadelphia, discussed the pathogenesis of these two conditions. In his experience pressure upon the cerebrum exerts a great part of the influence in producing symptoms. It is possible by the injection of large amounts of salt solution to produce the characteristic amaurosis and other symptoms of uremia even though there may be no poisonous products present. Not in-

frequently when pressure symptoms are relieved, the patient becomes better. The characteristic symptoms of headache, sleepiness, nausea, neuralgia, tinnitus, aphasia, bladder and intestinal incontinence may all result from pressure. In a case under Dr. Willson's care, suffering with the typical coma, incontinence of urine and a distinctly urinous breath, when a needle was introduced into the spinal canal, the spinal fluid spurted out. After the removal of 26 c.c., the patient became distinctly better. Characteristic Cheyne-Stokes breathing ceased, though it recurred later. Next morning after another 10 c.c. were removed there was another period of relief of symptoms. This came at a time when the patient's conjunctiva was absolutely unresponsive to touch. Other treatment usual in such cases as hot packs had simply made the patient worse and purgation and nitroglycerin failed of action. Only lumbar puncture did any good. At the autopsy in this case the ventricles of the brain were found greatly dilated and the arteries gaped when cut because of the pressure to which they had been subjected. Dr. Willson considers that while there is a toxic element in uremic convulsions many of the symptoms are due to intracranial pressure, and as this can be relieved readily a hint for treatment is thus given. German observers have found some relief from lumbar puncture but not much lasting benefit has been obtained. The problem of treatment is somewhat simplified, but on the other hand it is evident that the infusion of normal salt solution, as suggested by some, with the idea of diluting the toxins present is absolutely contraindicated, since this would increase blood pressure and since injections of normal salt solution in animals have been sufficient to produce uremic symptoms.

Reflex Elements.—Dr. James Tyson said that the causation of uremia has long been disputed. There seems no doubt that there are toxic elements in the etiology, though probably other factors enter. Dr. Willson's presentation of the factor of intracranial pressure seems to deserve special attention. Dr. Tyson has considered that eclampsia may to some extent be a reflex somewhat as convulsions in children; that is to say, in a condition of not firmly established equilibrium of the nervous system, the number of nerve impulses carried to the central nervous system sets up so much irritation as to cause a spontaneous explosion of nerve force.

Eclampsia and the Liver.—Dr. Alexander Lambert said that as the result of a number of recent observations eclampsia has come to be associated in his mind with lesions of the liver. Often the fatal cases have not gone to the extent of acute yellow atrophy, but they represent a beginning stage of disaffection. In hyperemesis gravidarum the same thing seems to be true and leucin and tyrosin are found in the urine just as in acute yellow atrophy. The lesions of the liver are extensive, but seem to be found in all the cases. There seems no doubt that the convulsions of uremia and eclampsia are due to hypertension, but what causes this?

Hot Water Treatment.—Dr. Fenton B. Turck, of Chicago, said that he found very hot water preferable to very cold water for the treatment of amebic dysentery. He had used cold water at first, but found that in weak patients and many of those suffering from amebic dysentery it caused collapse. He found 115° F. not enough to cause disappearance of the ameba. With care, however, he has been able to have his patients stand injections of 131° F. This, of course, cannot be borne at once, but patients have to become accustomed to the temperature. Water at 105° F. is allowed to run in at first, and then after a time at 110° F., and then at 115° F., until after a certain number of sittings patients can eventually stand up to as high as 130° F.

Dr. Tuttle, in closing the discussion, said that he treats ulcers in the rectum locally with antinosine. It must be remembered, however, that no drug will reach the germs in the submucosa. As regards the objection that has been made that the suggested operation upon the appendix with the leaving of an opening into the cecum is too serious a consideration for the treatment of amebic dysentery; it must not be forgotten that while an amebic dysentery lasts there is always danger of the occurrence of liver abscess and that once this development has occurred, the case invariably runs a fatal course. An operation which should have no mortality even though it does involve considerable discomfort and inconvenience is not too high a price for a patient to pay for freedom from so serious a danger.

Tuberculosis and the Family Physician.—Dr. S. A. Knopf, of New York, said that the solution of the serious problem of tuberculosis in large cities depends mainly upon the family physician. Unless he is able to recognize the affection early and to begin the proper treatment there is little hope in most cases of the tuberculosis being discovered before serious pathological conditions have developed in the lungs. Dr. Knopf believes in the old-fashioned idea of a family physician to whose care is entrusted the health of the family. A time will come doubtless when he will be asked to examine members of the family at regular intervals, even though there may be no special need for treatment. It is especially important that for health's sake there should be periodical examination of the chest of each member of the family. Dr. Knopf said that undoubtedly the family physician would do much to prevent the evils which now flow from the immense consumption of patent medicines in this country. Many of the cough remedies so frequently advertised, and which patients are prone to take contain morphine and other drugs, which seriously injure the appetite and are the worst possible agents for a consumptive to take. On the other hand, many of the tonic remedies widely advertised are scarcely more than combinations of whisky with certain bitter principles. Some of the best known of the tonics, the sarsaparillas and remedies for women's ills contain from 25 to 45 per cent. of alcohol. This has been shown by the investigations of the Massachusetts Board of Health. Dr. Knopf said that quacks and others succeeded in obtaining testimonials by the most questionable methods. The patient who has recently been under his observation, and who is suffering from tuberculosis in its last stages, said that twice deceived by the fact that the great Professor Koch's name seemed to be attached to it, he had been tempted to take the Koch lung cure. After the course of treatment had expired and she was not able to pay any more, the physicians attached to this institution offered to treat her for a longer period free of charge, provided she would sign a testimonial that she had been examined by three reputable physicians and found to be in the last stages of consumption and had been cured by Koch's methods.

Appendicitis and Influenza.—Dr. Marvel, of Atlantic City, showed by a series of statistics that appendicitis seems to bear a certain relationship to grip. Examination of hospital records in Philadelphia in recent years seems to show that at times when grip is raging with greater virulence, there are more cases of appendicitis. There is an intestinal influenza which apparently weakens the resistance of the appendix, hence the acute inflammatory disturbance which results. Winternitz has seen many cases of appendicitis which he considers due to the influenza bacillus. Lucas Championnière, the distinguished French surgeon, considers that the etiological relationship between the two diseases is very close in many cases. Surgeons generally

who have been in communication with Dr. Marvel, are much more inclined to consider that there is a relationship between the two diseases than are medical men.

Dr. De Lancey Rochester, of Buffalo, said that it is unlikely that there has been more real influenza during the past five years than during the preceding five years, though, of course, there has been more appendicitis, because of the better diagnosis and readier recognition of the disease. It is an interesting subject for observation, but as yet nothing can be said.

Dr. Robert Morris, of New York, said that he considers influenza to be a prominent predisposing cause of appendicitis because the presence of the bacillus of influenza in the intestinal tract causes the swelling of the mucosa of the appendix and this leads to lowered resistive vitality, during which bacteria easily find a nidus for growth.

FOURTH DAY—JUNE 10TH.

Aneurism of the Innominate Artery.—Dr. A. P. Francine, of Philadelphia, reported in detail six cases of aneurism of the innominate artery collected from the 3,309 autopsies at the Philadelphia Hospital with two additional cases from the Pennsylvania and Episcopal hospitals. Besides this he gave the details of 138 cases collected from the literature. Among the symptoms of innominate artery one of the most prominent is the weakness of the right radial pulse. As a matter of fact, however, the pulsation in all arteries on the right side is weaker than on the left and the carotid is usually noticeably weaker, while the weakness in the right temporal is apt to be more noticeable even than in the right radial. As the result of the tumor there is nearly always diminished resonance at the apex of the right lung and there is distinct tactile fremitus near this increased resonance. The tumor of innominate aneurism is nearly always superficial. In its growth it sometimes forces out and upward the clavicle. Dysphagia is less prominent with this form of aneurism than with aortic aneurism and a curious feature is that this symptom is apt to be more prominent at the beginning than it is later, when the innominate tumor forces itself past the clavicle. The larynx and trachea are, however, more compressed than with aortic aneurism and the voice is more interfered with. There is a regurgitant quality of the right radial pulse which has been noted as pathognomonic of innominate aneurism.

Pathology of Arthritis Deformans.—Dr. Thomas McCrae, of Baltimore, said that the term infectious arthritis would better be limited to arthritis due to a specific organism. There is apt to be confusion without this. Whether arthritis deformans is due to a specific organism or not, is not yet decided. The important question in pathology is whether there are two distinct diseases, one producing hypertrophy and the other atrophy, or whether these are only types of a single disease. The relationship of these diseases to acute articular rheumatism is extremely doubtful if it exists at all. There is the history of cases in which after an attack of acute rheumatism fifteen years before arthritis deformans developed. The majority of the pathological descriptions are those of late changes in the disease, and in order to decide many of the important questions the earlier changes must be studied. Not all cases of arthritis deformans go on to joint deformity. Some of them are mild and get entirely well or so nearly well as not to be a source of inconvenience or unsightliness. In most cases, however, there is either an atrophy or a hypertrophy of joint tissues. Goldthwaite, to whom is owed most of the knowledge of the disease here in America, says that either of these forms may occur at any age from two to seventy years. Most authorities are agreed that at first there is synovial inflammation, followed by atrophic changes and later complete disorganization of the joints. Hypertrophic changes involving mainly the bone may occur after this and some observers have seen this succession of events, but there is yet some doubt about it. The same histological changes are noted in the joints as in other forms of arthritis as those due to the gonococcus or to certain of the pus cocci, or even to the tubercle bacillus. Periarticular changes are usually quite marked.

Hypertrophic Changes.—Dr. Garrod, the distinguished English authority on arthritic conditions of various kinds, who has had the advantage in this matter of seeing and knowing the histories of cases observed also by his father, says that he has never seen a progression from the atrophic to the hypertrophic form. The predominant feature of many cases, however, is a bony overgrowth accompanied by eburnation and erosion of cartilages. In most cases there is partial or complete involvement of the spine, with hypertrophy between the vertebræ, but also the deposit of bone in the ligaments of the parts. These deposits are apt to be curiously irregular as may be seen by specimens preserved in the English museums. While this disease has been described under the name of spondylitis, the spine is seldom affected alone, but usually there is also some involvement of the shoulder and hip. The term monoarticular has been used but this seems unfortunate, for the disease is typically arthritis deformans and is very seldom entirely confined to one joint, though the symptoms may be very prominent in one large joint. In these cases it is particularly the hypertrophic type that is seen.

Still's Disease.—This is an affection which has been described by the English physician, Still, as occurring in children from the age of two to five years, with polyarthritis, polyadenitis and enlarged spleen. There seems no good reason, however, for separating this affection from the rest of the group of acute arthritis deformans. Affections resembling Still's disease, as it occurs in children and with the same typical features, are noted in young persons over fifteen years when they are always considered as examples of arthritis deformans. The multiplication of terms then is without good reason. In certain cases the hypertrophic and atrophic form may coexist. The hypertrophic form being seen especially in the spine, the atrophic in the peripheral joints. There is question whether the disease is due to disorder of the nervous system or whether it is a specific infection, or due to multiple infection. The symmetry of the disease, its occurrence at the periphery and progress toward the body and the trophic changes in joints resembling those in Charcot's disease or in syringomyelia, seems to point to some central nervous disturbance. As a matter of fact, however, the disease is not so symmetric as is said and does not necessarily begin in the small peripheral joints as it may affect the large joints. There is absence of evidence to any involvement of the central nervous system, except in a few cases in which the cells of the anterior horns of the spinal cord were injured.

Specific Infection.—Recently certain microbes have been discovered supposed to be specific for the disease. They were isolated from the case and their injection after culture was followed by hypertrophic osteoarthritis in the rabbit. It remains to be seen whether this work will be substantiated by others. The possibility of a combination of infections must be borne in mind. The gonococcus may produce lesions very similar to those of arthritis deformans. In the 170 cases seen at Johns Hopkins Hospital, heredity seemed to be a predisposing factor. This was not marked, but, as in cancer, the affection seems to run in families.

More males than females were under treatment at Johns Hopkins, but this is the only list of over 100 cases in which this is true.

History of Arthritis Deformans.—Dr. James J. Walsh, of New York, said that the disease, while only recently separated from rheumatism, is very old. Mummies have been found with the distinct pathological changes of the disease. Virchow found bones in a medieval graveyard with signs of the affection. Botticelli's model seems to have suffered from the disease, and as he followed the outlines of her fingers closely in painting them the result is, he is accused of painting ugly hands. The English museums are rich in specimens of arthritis deformans from the last hundred years—before the disease was acknowledged to be distinct. English observers, especially such conservative authorities as Garrod, Hale White, and Bannatyne, consider that there are three forms of arthritis deformans from the clinician's standpoint. The first is a chronic deforming affection which occurs particularly in the smaller joints and gradually involves more and more until considerable disability results. This occurs a little more frequently in old women than in old men and is not very distinctly separated from Heberden's nodes, though this latter affection may after a time progress no farther than a certain amount of nodular deformity of the joints of the terminal phalanges and there is a well-grounded English tradition that sufferers from arthritis deformans are long lived. The second form of the disease is an acute affection resembling ordinary rheumatism in its onset, but running a febrile course of lower degree and not getting entirely well as does acute articular rheumatism. The third form of the disease is usually a deforming process limited to one large joint. The joint most commonly affected is the hip and after this the shoulder. This is the only form of arthritis deformans that is likely to attack men more than women.

Differential Diagnosis.—The important point in differential diagnosis is the recognition of acute arthritis deformans from acute articular rheumatism. Arthritis deformans occurs more commonly in young women, though it may affect young men. The temperature is usually not above 102° F. and sometimes during the course of the disease may not exceed 100° F., and yet there may be distinct swelling and tenderness, especially of the smaller joints. The disease affects by preference the small joints of the hand, or those of the toes, though it may invade other joints. In nearly all cases there is some involvement of the joints of the cervical vertebræ and also of the temporomaxillary joint. The most important differential sign is the involvement of the jaw. This may only proceed to the extent of tenderness over the joint, with some difficulty of mastication. The soreness in the neck may be attributed to spasm instead of to the true joint affection, but such it is. The prognosis of the disease is not very favorable. As a rule, it may be said when what seems to be acute articular rheumatism fails to respond to the salicylates in the matter of being less uncomfortable and when there are signs of exudation into the joints and thickening, which does not begin to disappear after ten days, the frank recovery common in rheumatic arthritis must not be expected. Usually quite a little deformity is left. This may gradually disappear, however, leaving a certain amount of thickening that makes movement awkward, but is not unsightly. Even where there has been considerable ulnar deformity of the fingers, practically complete recovery is not impossible. There is a distinct tendency, however, for the disease to recur. The first attack is seldom completely recovered from and within the year, usually within some months, there is another lighting up of the affection which leaves more deformity than before.

Predisposition.—The disease seems to occur with sufficient frequency in families, to speak of a certain predisposition to its recurrence. This seems to mean no more than that a certain congenital condition of joints is favorable to the beginning of the disease. As a rule, the affection occurs in overworked people, especially those who are confined much to the house. It occurs typically in young servant girls at times when they are run down in health and seems to have a special tendency to occur in such persons not long after they have removed into a new country. It has often been noted that anemia and other constitutional disturbances are not rare about this time and arthritis deformans occurs with more frequency than at other times. Most patients give a history of having been exposed to some inclemency of the weather, but not infrequently it will be found that this cannot be connected directly with the affection. Sometimes there is a history of preceding rheumatism, but usually this is found to be no more than neuritic and neuralgic pains without any of the real characteristics of rheumatism.

Treatment.—Clarence E. Skinner, of New Haven, Conn., said that the most important question is that of exact diagnosis. Arthritis deformans differs from arthritis due to the pyogenic microorganisms or the gonococcus and its prognosis is a little better. In the textbook reconstructives, potassium iodide, cod-liver oil, iron and health springs are the chief remedies. Dr. Skinner considers that the most important considerations in the disease are proper diet and properly regulated physical therapy. As a rule, patients come for treatment in a run down condition and not infrequently they have been advised by physicians to limit their diet. Meat has often been denied them, especially red meat. As a rule, however, it will be found that they digest very well and that the system is craving for the elements found in red meat. Limitation of diet should be made with regard to the starches, though not infrequently it will be found that there is a disturbance of starch digestion. They should be made to wear woolen clothing next the skin and should be encouraged after the acute stage of the disease has passed to use their joints. This should not go to the extent, however, of breaking up adhesions, as only evil results come from it. Massage is not only indicated, but is one of the most important methods of treatment. Probably the most important remedial measure is dry, hot air. This does not mean hot-air baths at 200, but hot-air applications at 400 to 450. Frequent sweatings and ordinary hot applications serve to weaken patients and relax tissues and do more harm than good. A hot-air bath at 400, however, given in a cylinder covering the body up to the neck, acts as a stimulant that somehow brings about amelioration of the arthritic condition. Certain of the tonic and alterative drugs seem to be of service in special cases and a proper selection must be made for the individual. Potassium iodide has advocates and iron and chloride of gold may be found useful. The salicylates serve to relieve pain in cases where acute rheumatism is engrafted upon the original arthritis deformans. In the form of aspirin this will sometimes decrease the discomfort. Where there is constipation salt laxatives must be freely used. Digestive disturbances lead to the need to be corrected; for local pain, hot applications such as the hot-water bag are of service. Static electricity seems to do more than any other form for the affection. The wave current, applied by means of sheet tin electrodes molded to the heart lessen the discomfort and add to the flexibility of the joints. For local fibrous enlargements, the static

spark does good and for neuralgic conditions, the static spark is also useful. D'Arsonval's high frequency cage has been highly recommended and there is helpful general stimulation in central galvanization. Vibratory stimulation by lessening the spasm of muscles connected with the affected joints often serves a very useful purpose.

Types of Arthritis Deformans.—In opening the discussion, Dr. Joel Goldthwaite, of Boston, said that while it seems advisable to do away with multiplicity of terms, certain types of disease must be recognized. There is not only atrophic and hypertrophic arthritis deformans but also an infective type. It is hard to differentiate the microorganisms that may be responsible for the conditions, so that the general term seems advisable. In certain cases an enlargement of the ends of the bones is followed by atrophy of joint structures because of decubitus, as the ends of bones are pressed together. With regard to Still's disease, this seems to belong to the infective type and may be seen also in adults. When the spine is affected it is especially the cervical spine that is involved. With regard to acute and chronic arthritis deformans there seems to be a definite distinction. Bannatyne, the English authority, says that some acute cases never become chronic and some chronic cases have no history of having been acute. Dr. Goldthwaite believes that heredity may prove a predisposing condition. This is not a direct inheritance of the infectious disease, but rather the joints are of lower vitality, which almost invites infection. Such inheritance is not unusual. Weak feet or flatfoot may be inherited and often runs in families. Other joint conditions may follow the same rule. Monoarticular arthritis deformans seems an unfortunate term, since the disease is very seldom confined to a single joint and investigation will usually show more or less involvement of other joints.

Gonorrheal Arthritis.—Dr. F. C. Valentine, of New York, said that arthritis deformans occurs with more frequency in women than in men. It is in women that the lesions of the gonococcus are more destructive and the microorganism is more likely to get into the circulation with metastatic consequences. It seems not unlikely that some cases of arthritis deformans are really gonorrheal in origin, or, at least, that this microorganism has provided the basis on which other affections arise.

Hot Air Treatment.—Dr. De Lancey Rochester, of Buffalo, said that even without the cumbersome hot-air apparatus, it is still possible to obtain good results in the treatment of arthritis deformans. Hot-air baths may be given in bed by means of a spirit lamp, and if followed by friction of the skin, relaxation need not be feared. Massage careful passive movements will also be found of service. The affection occurs not infrequently in stout people and in these particularly sweats and massage are likely to be of service. The regulation of diet should exclude sweets and not much starch should be allowed. Fresh green vegetables, which contain organic iron in a form readily available by the system should be freely used. Where there is any tendency to constipation, salines should be given.

Secondary Infections.—Dr. McCrae, in closing the discussion, said that the gonococcus is not an etiological factor in the production of arthritis deformans, though the joint symptoms in chronic cases of the disease may be lighted up after gonorrhea or dysentery or other infection, as regards the word chronic rheumatism, it should be employed only for the condition in which symptoms of acute rheumatism, keep recurring. As for instance, when a child suffers from acute arthritic symptoms, followed by chorea and then endocarditis and a relapse of the arthritic symptoms; the index of acute rheumatism is that it leaves no sequelæ. It seems probable that all cases of arthritis deformans are infective and that the triple division of the disease is unnecessary. As a rule the mistake is made of putting patients on a spare diet. Many patients as a consequence are seen in a run down condition. The rule, on the contrary, should be to have them take the fullest possible diet consonant with good digestion.

Uric Acid and Disturbed Metabolism.—The medical profession is in many cases a creature of words. Uric acid has long been a shibboleth. It is supposed to have solved many problems. At last it is about to be abandoned. In this matter of rheumatism words count for so much and metabolism, katabolism and anabolism, quite as blessed words as Mesopotamia, are constantly heard. Nothing definite is known in this matter—why fool with idle terms. The most important mistake that they have unfortunately introduced is the limitation of diet in all chronic joint cases. Dr. Walsh has seen within the last month the wife and daughter of a physician, each suffering from the painful condition at the base of the big toe that is so often noted in connection with flatfoot, who had been carefully dieting themselves for gout for more than a year. One result of the mixing up of rheumatism and arthritis deformans is the free use of the salicylates, which always do more harm than good, since they destroy red blood corpuscles, make the patient more anemic and do not relieve pain. It has been objected that until the microbic cause of rheumatism and arthritis deformans is known, there is no justification in entirely separating the diseases. At the beginning of the nineteenth century there was in the measles and scarlet fever group of diseases, as yet undifferentiated from one another, what have now come to be recognized as four distinct diseases: Scarlatina, measles, German measles and Duke's, for fourth disease. Of none of these is the microbic cause known? Surely no one would say that there is no justification for their clinical separation.

Hot Air Applications.—Dr. Skinner said that hot air at low temperatures and hot air locally applied, had not given satisfaction in his hands. Local hot air even seemed to add to the pain. As a rule, for the severer cases of arthritis deformans, sanitarium treatment is needed.

Gonorrhea and the General Practitioner.—Dr. Ferd. C. Valentine, of New York, said that the general practitioner is as competent as the specialist to treat gonorrhea so long as the disease presents no serious complications. By treating patients at once, the general practitioner has the opportunity for successful abortive treatment, which is not often afforded a specialist. Not infrequently the reference of the patient to a stranger specialist adds to and emphasizes the neurasthenic symptoms which so often complicate the disease. The irrigation treatment may be carried out even in the office of the general practitioner without danger to himself or his patient and without the necessity for soiling floor or office furniture. Dr. Valentine considers that it would be advisable if so many cases were not at once referred to the genito-urinary specialist.

Convalescents from Tuberculosis.—Dr. A. Mansfield Holmes, of Denver, Col., said that the treatment of consumption, when the disease is taken sufficiently early, is now known to be reasonably successful. No one pretends, however, that the cured tuberculosis patient is likely to be free from the disease for long, unless he takes good care of himself. He cannot, for some years at least, work as hard as others without danger of relapse. It seems important that besides sanitariums for the treatment of tuberculosis, arrangements

should be made for outdoor life for convalescents from this disease for several years after their cure has been effected. This is the main problem that must be met now in connection with sanitarium treatment.

SECTION ON PEDIATRICS.

Second Day—June 8th.

(Continued from Page 1198.)

Congenital Occlusion of Lacrimal Canal and Acute Contagious Inflammation of Conjunctiva.—Dr. John E. Weeks, of New York, said that this condition was frequently mistaken for conjunctivitis, because of the pus which usually forms at the mouth of the duct. Differential diagnosis is to be made by bacteriological examination of the pus. Of the treatment he said time should be allowed possibly two or three months, for nature to open the duct, but if this does not occur the duct should be opened by instrumentation. He said that acute contagious conjunctivitis in infants is due to infection by one of four organisms, the gonococcus, the pneumococcus, the Klebs-Löffler bacillus, or the Koch-Weeks bacillus, that the value of differential diagnosis was important because of the assistance which this gave in treating the condition in the eye as well as the original site of infection and in the management of epidemics. The virulence of the conjunctivitis, he said, could not be depended upon as an indication of the form of the infection, as there were cases of gonorrheal ophthalmia which were so mild that they might be mistaken for ordinary muco-purulent conjunctivitis, but that these same cases were capable of setting up severe ophthalmia in other individuals or of the opposite eye in the same individual. The treatment of the different forms of conjunctivitis should be cleanliness obtained by the use of boracic acid solutions and the proper application of cold or heat being governed in this by the form of the infection—cold acting best in those cases which are due to organisms which grow best at high temperatures, this he said was particularly true during the early stages of the disease. The diphtheritic form should, of course, be treated by antitoxin injections. The silver preparations are useful in the gonococcus infection, but local treatment should be exercised not to interfere with the nutrition of the cornea.

In discussing Dr. Claiborne's paper Dr. Bennett, of Buffalo, said that in examining the eyes of truant children he had found a large percentage of refractive errors, thus in a measure accounting for their lack of interest in their school work and said that in several cases of persistent vomiting he had found the cause in the eyes of the patient.

Dr. Jarecky, of New York, said that he had followed up many cases of chorea treated at the German Policlinic and that correction of refractive errors in these cases had not been followed by improvement in the choreic symptoms in a single case. Glasses, he said, which are used to correct astigmatism in children, should be worn only temporarily and should be considered merely one of the resources at our command for restoring the child to normal condition.

Enuresis.—In a report of cases observed in dispensary practice, Dr. Maurice Ostheimer, of Philadelphia, said that Dr. I. Valentine Levi and himself had formed these conclusions: That while there is no single cause of enuresis, reduced tone of the sphincter muscles is present in most cases and that this is often the result of some antecedent or simultaneous illness. Among the many methods of treatment they found that in the vast majority of cases recovery followed the administration of the tincture of belladonna in ascending doses in the mild cases and of atropine and strychnine in the intractable cases. In the latter treatment they had begun with atropine gr. $^1/_{240}$ and strychnine gr. $^1/_{480}$ to one drop of water gradually increased until incontinence ceased and continued at the highest dose for from two to four weeks, and then gradually descended so that the entire treatment usually covered from six weeks to four months. The ingestion of fluids after supper was stopped and errors in diet were corrected in all cases. Daily cold sponge baths of two minutes' duration were given, and if hyperacidity of the urine had been present potassium citrate had been given and if phymosis existed circumcision was performed.

Bacteriology of Summer Diarrhea.—Dr. Wm. H. Park, of New York, pointed out the great difficulty of finding the specific bacterial cause of any given case of diarrhea because of the large numbers of organisms present normally in the intestines, many of which are not ordinarily inimical to health, but which under conditions occasionally arising might be productive of severe diarrheic symptoms. He said that of the enormous numbers of bacteria always present only a very small number of forms was pathogenic, and of these the ones studied closely resembled the colon bacillus in their biocultural characteristics that great difficulty had been experienced in isolating them. The term colon bacillus, he said, covered a great group, some varieties of which were pathogenic and developed at times at the expense of the other forms producing a diarrhea. The Shiga bacillus which had been isolated from the stools of dysentery patients in Japan was not the same as the dysentery bacillus found in this country, which, however, it closely resembled. In regard to the serum treatment of dysentery he said that results had been unsatisfactory presumably because when inflamed conditions exist in the intestinal tract it is practically impossible to counteract the activity of all of the pathogenic organisms present.

Infantile Dysentery.—Dr. J. H. Mason Knox, Jr., of Baltimore, analyzed 43 cases in which the *Bacillus dysenteriæ* (Shiga) had been found in the stools. These showed that the infection was borne by some common carrier and a close study, he said, had practically excluded previous conditions as to surroundings, foods, etc., and that drinking water was no doubt the means by which the bacillus entered the body, although the possibility of the house fly as an infecting agent must be considered. The Harris acid-mannite organism, so-called, was found in each case, but the clinical picture varied greatly, two general types occurring, however, one in which profound toxemia was present, the other being characterized by the severity of the bowel symptoms with mucous or bloody diarrhea. This difference in the symptoms may be due to the greater or less activity of other bacteria, *e.g.*, streptococci or staphylococci.

Bacillus Dysenteriæ and Infantile Diarrhea.—A study of 237 cases by Dr. L. Emmett Holt, of New York, showed that the bacillus may act pathogenically not only in summer but also during the winter months, and diarrhea occurs as a result both in children previously healthy, and in those already more susceptible because of disease, it occurs in various forms and under all conditions but previous conditions were found to have influenced the course of the diarrhea, as for example, 26 of the cases were breast-fed babies and presented milder symptoms and offered greater resistance to the disease, while of the 73 fatal cases the majority were among the hospital type of patients. In the management of diarrhea Dr. Holt advocated the withdrawal of milk as an article of diet particularly in

the severe cases, and because of the probable infectious character of the discharges from the bowel these, he said, should always be disinfected. He urged further study of the serum treatment and expected favorable results from its use in those cases of diarrhea in which the problem is to treat the infection and not the general condition which was present in so many cases before the acute symptoms occurred.

Diarrhea in Children.—Dr. J. C. Cook presented a study of 29 patients in the investigation of which he had attempted to prove a connection between the bacteria in the buccal cavity and those present in the intestines. His results were negative.

Management of Summer Diarrhea.—Dr. Thomas S. Southworth, of New York, said that this should begin before hot weather by hygienic and dietetic prophylaxis. The danger he said among infants was chiefly in proportion to artificial feeding and the greatest safety is secured by heating the milk, however, pure. Among older children errors in diet as well as bad milk are exciting causes, but local conditions and lesions once started are progressive and are intensified by a milk diet and under these conditions toxemia is the prominent factor. In severe cases prompt elimination of milk from the diet reduces the mortality. Opium should be used only to control excessive peristalsis. During the discussion of the foregoing papers on summer diarrhea the value of the so-called water treatment of the French physicians was emphasized, but that, because of differing social conditions, the substitution of barley water for plain sterile water was preferable in this country; that attention to absolute cleanliness, preliminary flushing out of the bowel, followed by the "starvation" plan of treatment with little or no opium, followed by gradual resumption of a carbohydrate diet, were the chief factors in the successful treatment of summer diarrhea in children.

Landry's Paralysis.—Dr. Henry Enos Juley, of Louisville, Ky., reported a case of this little known disease and suggested the possibility of a specific organism as a cause.

Hematuria in Infantile Scurvy.—Dr. John Lovett Morse, of Boston, said that although hematuria was generally considered an unusual complication of scurvy it is in reality a frequent symptom, that hematuria in a child accompanied by tenderness along the spine and elsewhere was a sufficient cause for making the diagnosis of scurvy, particularly if it cleared up upon the administration of antiscorbutic treatment—orange juice being the most frequently used in his practice.

Dr. Stowell, of New York, said that the hematuria of scurvy and the hemorrhages into the skin are probably due to a common cause, possibly a specific germ.

Intestinal Obstruction in Children.—Dr. John F. Erdmann, of New York, said that obstructions are due to intussusception, strangulated hernia, post-operative bands or Meckel's diverticulum. Intussusception, he said, was not a common cause and when it is met with it is not the sausage-shaped tumor of the text-books. Frequently it closely resembles floating kidney, or appendicitis and differential diagnosis may not be possible till laparotomy is performed. The symptoms were, he said, severe, sharp, colicky, abdominal pain, recurring periodically with an elevation of temperature. Treatment of this condition is mechanical, which consists of attempts to reduce it by enemas, but this should never be continued longer than six hours, after which operative treatment should follow. The danger in depending upon injection lies in the liability to reduce all of the intussusception except the part at the iliocolic junction and having at the same time a subsidence of symptoms, but which would be followed by more severe symptoms later when the remnant of the intussusception became gangrenous. In spontaneous reductions or those produced by injections the test of the completeness of the reduction should be the passage of a large bowel movement.

Dr. Abt added one other form of obstruction to the foregoing classification—that due to paralysis of the gut during the course of a profound disease elsewhere, such, for instance, as occurs in pneumonia; ptomaine poisoning may also simulate intestinal obstruction.

Dr. S. W. Kelly, of Cleveland, Ohio, said that if seen early spontaneous reduction might follow the use of opium, and that in the treatment by enema pressure of four or five pounds continued for fifteen or twenty minutes beginning with air and following this by water often produced a complete reduction where less pressure or pressure withdrawn after a shorter period of time might not effect a reduction.

Dr. Erdmann said, in closing, that he had always found great difficulty in keeping either the air or the water in the gut and that too great pressure was dangerous because of the weakened and edematous condition of the gut wall, but injection at the time of the operation was helpful.

Perinephritis in Children.—Dr. Wisner R. Townsend, of New York, said that this condition is rarely diagnosed correctly, and almost never before the formation of an abscess, but differentiation he said is possible. The conditions for which it may be mistaken are Pott's disease or hip-joint disease from which it may be diagnosed by the difference in the appearance of the stiffness about the part affected in the former and in the immobility of the hip-joint in the latter, from lumbago in the absence of leucocytosis in this, while an increasing leucocytosis occurs in perinephritis. The treatment, he said, is expectant—rest in bed and milk diet, till abscess formation, then it should be operated upon.

Dr. Jacobi called attention to the etiological importance of constipation in this condition.

Diagnosis of Enlarged Bronchial Lymph-nodes.—Dr. Alfred Friedlander, of Cincinnati, said that although great difficulty is present in making a diagnosis of this condition, the enormous frequency of tuberculosis of these glands, as shown by the post-mortem examinations made even a presumptive diagnosis of vast importance. Of value in this connection is a peculiar paroxysmal cough similar to that of pertussis but without the blowing inspiration, dyspnea or exertion with no heart lesion, hoarseness, with the general indications of a tuberculous condition, all these, with possibly evidences produced upon palpation and percussion over the mediastinum will give highly presumptive indications of tuberculous glands. The possibility of an enlarged thymus gland must not be forgotten, and also that enlarged bronchial glands may occur in pertussis and in measles. He said also that he had found in ten cases in which there were clinical symptoms of enlarged bronchial lymph-nodes, a reactionary lymphocytosis. He hoped further investigation might prove this a more certain method of diagnosis in this condition.

Dr. T. W. Kilmer, of New York, said that the cough, such as had been mentioned by Dr. Friedlander, was frequently due to abnormal retropharyngeal conditions.

Early Aural Examinations in Acute Diseases in Children.—Dr. James F. McKernon, of New York, said that middle-ear complications are far more frequent than is generally observed, that if aural examinations were regularly practiced as a part of every physical examination the cause of continued elevation of temperature after other symptoms had subsided

would be more frequently found. It is a fallacy, he said, to think that pain is always present in otitis media since a large percentage of cases never have any pain at all and careless otoscopy may not reveal the true condition of the drum. As an example of deceptive appearances he described a condition in which there was apparently a normal drum, but upon touching it with a probe, that which had seemed the drum was only a desquamated flake of epithelium which crumbled and came away, revealing an inflamed drum behind.

Dr. Fischer, of New York, said that he had frequently observed cases of acute disease in children in which there had been a subsidence of all symptoms except restlessness at night, the patients having normal temperature and pulse. This had been followed by spontaneous perforation of the ear drum and a discharge of pus with a complete clearing up of symptoms. Too frequent irrigation of the nasal passages, he thought, was a frequent cause of middle-ear disease.

Dr. Kerley reviewed 51 cases of acute otitis media in children, in 34 of which there was no pain or local manifestation; the only reason for making an aural examination being an elevation of temperature.

Dr. McKernon further said that if the ear drum bulges at all it should be incised at once, and there were many cases in which because of the danger of jugular bulb, or mastoid involvement paracentesis should be done even before bulging occurs. He said also that those cases of mastoiditis which had not been operated upon for the purpose of evacuating the pus usually resulted in deafness.

Some Physical Signs in Children not Sufficiently Emphasized.—This paper, read by Dr. Samuel McClintock Hamill, of Philadelphia, gave the results of observations made by himself and Dr. Theo. LeBoutillier on a large number of normal children. Of the lung they found the following conditions peculiar to children: (1) An area of impaired resonance under the left clavicle. (2) An area over the root of the lung in which there is a transmission of bronchial type of breathing. (3) Position greatly influences the percussion note. Of the heart: there was found a slight difference in the outline of heart dulness, but more marked was the fact that up to the sixth year the apex beat was found in the fourth interspace in the midclavicular line.

Hernia in Infancy.—Dr. Wm. B. Coley, of New York, said that the question whether the treatment of hernia in children should be mechanical or operative should be answered only when all conditions surrounding the individual child had been considered. If the child could be properly cared for and watched to see that the truss was kept in position then this method should be tried up to the age of four years. If, however, the truss does not retain the hernia, or if the hernia is irreducible or there is an accompanying hydrocele, or, if strangulation occur, a radical operation should be performed. If after trial of mechanical treatment up to the fifth year there is no cure of the hernia then operative treatment should follow. If seen after this age for the first time, and there has been no treatment by means of a truss, the peculiar conditions present must be considered in deciding upon the best treatment. In the treatment of umbilical hernia, the use of a flat button covered with soft cloth should be applied over the umbilicus and held in place by means of adhesive plaster. The Bassini operation is the one preferred by Dr. Coley, using, however, kangaroo tendon instead of silver wire as sutures and transplanting the cord as is the custom of most surgeons at the present time. He said that the belief that malignant disease is liable to occur in an undescended testicle was not upheld in his experience as he had seen only one case of this in an experience of 1,260 cases operated upon, and that there had not been one case in the 60,000 recorded at the Hospital for Ruptured and Crippled. Strangulation, he said, is comparatively rare in children and when it does occur it is due to adhesions and does not occur at the neck of the sack. As to the results of operative treatment in children the risk is very small (less than one per cent. of infections at the site of operation since the advent of rubber gloves, and only four per cent. before that), and as any operative treatment will be more productive of good results in the child than in adults the chances of permanent cure are practically certain.

Chorea.—Dr. W. C. Hollopeter, of Philadelphia, said that there is now less chorea than there was fifty years ago, and that this was due to the improved hygienic surroundings of the child. Much is said about the excess of school work put upon the child of to-day, but he thought that this was overvalued in its causation of chorea, the effect of poor personal hygiene in the home surroundings, irregularity in daily life, overfeeding, etc., being more potent. One writer on the etiology of chorea has said that it is a brain disease, while the relation between rheumatism and chorea is an interesting question not yet settled. The most important contribution to the knowledge of this disease has come from the discussion at meeting of the British Medical Association in July, 1903, the essence of which was that chorea is a disease of microbic origin. A diplococcus has been isolated from cases of chorea and there seems to be reason for the belief that this is implanted upon a previous micrococcus infection making, if this is true chorea, a mixed infection. A diplococcus has also been isolated from rheumatic patients which is believed to bear a close relation to that of chorea.

In the treatment of chorea, Dr. Hollopeter has abandoned the use of specific drugs and depends upon prolonged warm baths. These he gives twice daily, each one lasting from one to two hours. The temperature of the bath should be such as to give the child no unpleasant sensation (usually from 90° to 98° F.). From this temperature it is cooled down till it soothes the whole cutaneous surface. After the child has been in the bath for the required time gentle massage is given and the child dried and allowed to sleep. In from 50 to 60 cases treated in this way he has reduced the duration of the attacks from three months to six weeks.

Nasal Affections of Children.—Dr. Louis J. Lautenbach, of Philadelphia, said that children are great sufferers from obstruction of the nostrils. They are very prone to diseased conditions affecting the nose and occluding the passageway. The mischief thus occasioned is common, and unfortunately often very serious to the life of the child as well as to its health. Along the respiratory apparatus tonsillitis, pharyngitis, laryngitis, but particularly bronchitis and pneumonia, are commonly so caused—in great part by the mouth-breathing. Stomach and intestinal disorders are frequent results of nasal disease. Nervous affections and lack of mental and physical development are by no means unusual. General lack of vitality and that indefinable something called a cold are frequent results. Lack of development of the dental arches and irregularities in tooth formation as well as placement can very often be traced directly to nasal disease, the widespread mischief thus caused lasting often through life. An impartial, unbiased examination will nearly always develop a satisfactory diagnosis. The connection between secondary conditions and the primary cause may not be clear, but when once understood the local and general treatment can be instituted harmoniously and

the results will more than repay for the difficulties encountered. Fortunately nasal troubles are easily cured as a rule.

Myxedema and Diabetes Mellitus.—Dr. A. A. Strasser, of Arlington, N. J., made a very complete report of this unusual combination.

SECTION ON NERVOUS AND MENTAL DISEASES.

FIRST DAY—JUNE 7TH.

The meeting was called to order at 2.15 P.M. by the Secretary, Dr. David I. Wolfstein, of Cincinnati.

Resolutions on Dr. Pearce.—Owing to the death of Dr. F. Savary Pearce, Dr. Howell T. Pershing, of Denver, Col., was elected Temporary Chairman, and there was no Chairman's Address. A committee composed of Drs. Charles K. Mills, Philadelphia; Richard Dewey, Wauwatosa, Wis., and W. J. Herdman, Ann Arbor, Mich., was appointed to draw up resolutions on the death of Dr. Pearce, and a similar committee on the death of Dr. Orpheus Everetts, of Cincinnati, Ohio, was composed of Drs. F. W. Langdon, Cincinnati; Hugh T. Patrick, Chicago, and Dr. Brainerd.

Public School and Health.—The report of the Committee on the Collection of Information Regarding Public School Methods and Their Effects upon the Mental and Physical Health of School Children was read by Dr. W. J. Herdman, of Ann Arbor, Michigan, the committee consisting of Drs. F. Savary Pearce, James McBride, Hugh T. Patrick, C. H. Williams and W. J. Herdman. He reported that the collection of the data on this subject was as yet incomplete and considered (1) the medical examination of the child at the time it enters upon school life, and (2) the examination during the years thereafter. There are many other factors such as the hygienic and sanitary surroundings in the schoolrooms and buildings, which have to be eliminated before the schools methods can be charged with affecting the health of the children. The work in this and other countries was reviewed and particularly considered under the following subdivisions: (1) Inspection of pupils and teachers with a view to detecting any contagious or infectious disease; (2) investigations of the sanitary and hygienic conditions of the school buildings, rooms, equipments and environments; (3) examination of individual pupils, especially those who have attracted attention by deficiency in hearing, eyesight, etc. The material decrease in the contagious and infectious diseases among school children in New York, Philadelphia, and other cities since the institution of medical inspection in the schools was commented on with favor. Upon motion of Dr. C. B. Burr, Flint, Michigan, this report was accepted and the committee continued.

SYMPOSIUM ON CHOREIFORM AND OTHER SPASMODIC MOVEMENTS.

Symptomatology, Pathology and Treatment of Choreiform Movements.—This paper was read by Dr. William G. Spiller, of Philadelphia, in which he considered at length the clinical aspects of Sydenham's chorea, Huntingdon's chorea, posthemiplegic chorea, postapoplectic hemihypertonia athetosis and pregnancy occurring during pregnancy, laying particular stress upon the latter condition and also upon the time of life at which the disease was most likely to occur, the pathology of the two former conditions being carefully discussed. In the treatment, he considered rest in bed of paramount importance, and went fully into the details of the arsenical treatment, in which the patient should be carefully watched for symptoms of neuritis, and with which the best results are obtained when the drug is employed during the first three weeks of the disease. A report of 180 cases of this disease before the Moscow Society for Diseases of Children was referred to, 86 of which were treated with arsenic, and in these the best results were secured, the others being treated with rest, antipyrin, bromide and quinine, the least useful being the two latter drugs.

Convulsive Tic.—This paper was read by Dr. Hugh T. Patrick, Chicago. The writer belived this condition to be very common but frequently misunderstood. The characteristics of the disease were fully discussed, and the points of differentiation between it and chorea, spasm, paramyoclonus and myoclonias, abnormal movements dependent upon hallucinations or delusions, stereotypic and excessive gesticulation outlined in detail. The two principal factors upon which the prognosis depends are the nature of the disease and the nature of the subject, and while the prognosis in children is usually good, it is a most rebellious disease. He referred to one case in which prolonged artificially induced sleep had been of considerable value, while in another the same success had not been attained. The causal factor should, if possible, be found and removed, after which, in children especially, stimulation of inhibition by means of rewards for controlling a spasm and punishment for not doing so, are of value; the latter, however, must be slight as cases were referred to in which untoward results had been caused by severe punishment.

Hysterical Movements.—This paper was read by Dr. Howell T. Pershing, of Denver, Col., who stated that he believed the morbid process to be an excessive reaction due to morbid ideas and motions occurring in the higher cortical centers. The differential features of the mode of onset, and the general character of the movements were considered, the author stating that he believed a pysychic origin could generally be traced. The highly coordinated movements, such as saltatory spasm; the hysterical imitations of chorea, hysterical blepharospasm, hysterical imitations of Jacksonian epilepsy and hysterical torticollis were considered in detail seriatim, followed by suggestions as to prognosis and treatment, in which the mental influence is of paramount importance, and which must be guided by the ideas applicable to the treatment of chorea in general.

Dr. Charles K. Mills, of Philadelphia, in opening the discussion, considered Sydenham's chorea due to infection caused by the action of toxins on an exhausted nervous system, while Huntingdon's chorea came under the developmental or family type. Rest and hygienic treatment he considered of paramount importance, and the drugs which are of the most importance are those which tend to restore the tone to the nervous system.

Dr. B. Onuf, of Sonyea, N. Y., reported a case of spasm of the retina, recti muscles and pupils, which the patient began when an oculist prescribed for her white glasses, prior to which time she had been wearing colored glasses, and which he attributed to hypersensitiveness of the retina due to frequent accommodation, the light being too strong to be borne so soon as slight dilatation took place.

Dr. McGregor, of Saginaw, Mich., referred to the cases of chorea resulting from fright, several of which he related and also reported one case in which the condition disappeared upon the removal from the patient's diet of veal and reappeared eighteen months later, when this article of food was again indulged in.

Dr. Hamilton, of Independence, Iowa, referred to the work which he had done at the State hospital for the insane at that place, and gave the mode of death, clinical and pathological findings in several cases. He also reported a case in which the condition had been present in

all but two of the female members of the family for three generations, never being noticed until pregnancy, and the two exceptions were never married, although he inclined to the opinion that the chorea was present before the advent of pregnancy, which simply aggravated its manifestations.

Dr. D. J. McCarthy, of Philadelphia, reported the clinical and pathological findings in several cases, and also referred to one case which had been considerably benefited by suggestive therapeutics for a time, but afterward relapsed.

Dr. John Punton, of Kansas City, Mo., referred to a man who had been operated on five times for tic, and in whom he had a surgeon who had suggested the advisability of removing the gasserian ganglion, which was cured by means of suggestive therapeutics.

Dr. John W. Rhein, of Philadelphia, reported the pathological findings in a case of chorea dying during the second week of the second attack of the disease, in which there was some change in the muscles, but no demonstrable lesion in the spinal cord or cortex. He also referred to the possibility of the occurrence of choreiform movements in locomotor ataxia.

Dr. Wharton Sinkler, of Philadelphia, said that there was too much of a tendency to include under one general heading the conditions due to different causal factors.

These papers were further discussed by Drs. C. H. Williams and W. C. Jones, of Texas, and closed by Drs. Spiller, Patrick and Pershing.

Second Day—June 8th.

Nature of Traumatic Sclerosis.—This paper was read by Dr. A. C. Brush, of Brooklyn, who after referring to the fact that the earlier observations indicated organic disease and to the physiological experiments of Mendel, Schmaus, Berkeley and others, stated that at the present time it is a question whether the effects of trauma on the nervous system are due to conditions of grave hysteria, functional neurosis or to a type of multiple sclerosis. This was followed by a careful résumé of the literature on the subject; a report of his personal clinical observations in fifteen cases, particularly differentiating between this condition and true hysteria and pseudosclerosis described by Westphal and Strümpell; and a report of the pathological and microscopic findings in five cases, particularly outlining the differences between traumatic sclerosis and multiple sclerosis. In conclusion, he stated that his opinion coincided with that of Strümpel that traumatic sclerosis is different from multiple sclerosis and that the weight of evidence is in favor of a distinct organic entity.

Dr. Angell, of Rochester, N. Y., referred to the frequently long duration of these cases, during which time they were lost sight of and the consequent scarcity of pathological findings thereon. He urged the elimination of the idea of a specific form of nerve injury in the examination of the case and that such examination be similar to that in any other case of spinal trouble, irrespective of the cause. A case developing marked disturbance of the muscular apparatus six months after injury in a railroad wreck, at the time of which there was no apparent injury, was cited as showing that primary degenerative changes were no doubt minute, while the secondary changes are quite extensive. Another case illustrating the opposite type was cited, where the patient suffered from marked hysteria between the date of the collision and the trial, after which he gradually became well. He believed that only in a small minority would we find elementary pathological changes.

Dividing Line Between Neuroses and Psychoses and the Position of Neurasthenia.—This paper was read by Dr. Richard Dewey, Wauwatosa, Wis., who discussed at some length the question of a dividing line between neuroses and psychoses, and stated if there was such a line, insanity was to be found on both sides thereof. He discussed fully the meaning and use of the term insanity and believed psychoses to be a preferable term thereto, following this by remarks on the proposition to treat neurasthenia as a psychosis and the classification recently proposed by French writers and more recently followed by C. L. Dana.

Campaign Against Insanity.—Dr. W. J. Herdman, Ann Arbor, Mich., considered the various forms of the disease and prospects for the cure thereof, and the etiology of the condition. He then reviewed the work that had been done in the United States and other countries for the study and treatment of the condition, consisting in some instances of special hospitals, in other of special wards, where the pathologists, clinicians and laboratory workers can combine their efforts, particular mention being made of the work in New York, Scotland and Michigan. He believed that the field of experimental pathology had much promise in it, but that the comparison of the mental status of the insane with that of the healthy person was the surest approach to the solution of the problem.

Dr. Searcy, of Alabama, believed the term psychosis to be much preferable to lunacy, insanity, *non compos mentis*, etc., particularly in view of the fact that in the courts of law alone lies the power to declare a man legally insane. He then classified the psychoses into the defective type, such as the manias, melancholias and phobias, and the erratic type, such the neurasthenias, hysterias, paranoias, moral delinquencies and moral perversities; and the drink and drug habits.

Dementia Præcox.—Dr. F. X. Dercum, of Philadelphia, after reciting his objections to the term, among which were the fact that many of the cases recovered, he stated that he preferred the term insanity of adolescence. He then outlined in detail the points of similarity and difference between hebephrenia, katatonia and dementia paranoides, and considered at some length the prognosis of each thereof.

Dr. F. W. Langdon, Cincinnati, Ohio, remarked upon the inappropriateness of the term dementia præcox in those cases which developed at thirty, forty or fifty unless the inception could be traced back to earlier years, which objection he felt was also applicable to the term "insanity of adolescence."

Dr. F. X. Dercum, in closing, emphasized the importance of keeping the earlier cases by themselves rather than placing them in the same group with the older ones.

(To be Continued.)

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Adolescence; Its Psychology. By G. Stanley Hall. Two volumes. 8vo, 770 pages. D. Appleton & Co., New York.

Graves' Disease Without Exophthalmic Goiter. By Dr. W. H. Thomson. 8vo, 143 pages. Wm. Wood & Co., New York.

A System of Practical Surgery. By Drs. von Bergmann, von Bruns and von Mikulicz. Volume II. Translated and edited by Drs. W. T. Bull and C. P. Flint. 8vo, 820 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

INDEX

Abdomen, upper, the association of surgical lesions in the, 1111
Abdominal drainage, 1147
pain of intestinal origin, 289
ring, internal, unsuspected irritation of, 953
signs, deceptive, 557
sympathetic, paralysis of, following labor, 311
versus vaginal hysterectomy, 983
Abortion, etiology and medical treatment of, 1007
medicolegal aspects of criminal, 1007
the surgical treatment of, 1007
Abortive treatment of gonorrhea in the male, on the, 488
Abrahams, R., sea-bathing in some forms of skin diseases, 593
Abrams, Albert, the tracheal traction test as an aid in the recognition of the asthmatic lung, 1207
Abscess, postpartum tubo-ovarian, 1023
surgical treatment of pulmonary, 422
tardy, of the liver, 1082
Abscesses, multiple, of the omentum, 1150
Absorptive capacities of the skin, the, 987
Academy of Medicine, American, the president of, 1182
Acapnea, a result of lowered barometric pressure, 212
Accessory sinuses, the prevention of diseases of the, 958
Accidents, railway, during 1902, 37
Accouchement forcé, the difficulties and dangers of, 1150
Aceton-content of the organs in cases dead from diabetic coma, the, 937
Achylia gastrica, 1138
Acid creamless milk in gastro-enteritis, 214
fast bacteria, resistance of, 798
salicylic, harmful, 79
Actinomycosis, cause of human, 216
of jaw, 179
progress in, 1200
Action of drugs on the coronary circulation, 359
physiological, and chemical constitution, relations between, 408
Addison's disease and frequency of urination, 524
disease, the adrenal in, 1001
Adenitis, treatment of cervical, 557
Adenoid operations and mortality, 518
operations at home, 518
Adenoids and adenoid operation, 1182
Adenoma, malignant, of the liver, 1000
of sweat glands, 798
Adhesions in brain surgery, the use of silver foil to prevent, 422
Adirondack Cottage Sanitarium, 364
Adjuvant, steam valuable, 525
Adrenal, function of, 1001
gland infusion, 808
in Addison's disease, the, 1001
Adrenalin, brief action of, 949
treatment of surgical shock with, 123
Adulteration, food, in New York State, 175
of foods, legal action regarding, 711
After-treatment of intranasal operation, 164
Agglutination phenomena of the staphylococci, 652
test in typhoid, improved technic of, 940
Agglutinins, experiments upon, 717
specific and non-specific, 716
Agraphia and aphasia, 282
Aids, laboratory, to diagnosis, 259
Air-cushion in surgery, an improvement on the, 855
Air cystoscope, 425
embolism, 215
and feeding in pneumonia, 526
water and unbreathed, 525
Albumin, a new method of determining, 455
in the feces, presence of, 795
Albuminuria as an accompaniment of diabetes mellitus, 212
cyclical, 211, 358
of puberty, 161
physiological, 499
postural, 358
Albuminuria, value of, in differentiating pyelitis from cystitis, 32
Albumoses and peptones, 173
Alcohol and metals, action of, upon the sea urchin, 359
and other drugs, 378
as a cause of locomotor ataxia, 1129
ether and chloroform on natural immunity in its relation to leucocytosis and phagocytosis, 757
in medicine, the prohibition of, 416
on resistance to infection, 939
problem, a novel aspect of the, 459
Alcoholism and arteriosclerosis, 1143
and degeneration, 701
ergot in, 445
Aldrich, Charles J., fracture of the base of the skull as a cause of epilepsy; report of case, 979
Alexian Brothers' Hospital, report of the, 317
Alloxuric bases in aseptic fevers, the, 606
Allport, Frank, the relationship existing between ophthalmology and otology and dentistry, 730
Altitude on blood corpuscles and blood plates, effect of, 383
Alumni Association of St. Luke's Hospital, the, 755
Association of the College of Physicians and Surgeons, New York, 225, 992
Amaurotic family idiocy, 716
Amblyopia, possible etiological factor in tobacco-alcohol, 218
American Academy of Medicine, 664
Association of Pathologists and Bacteriologists, 664, 711, 715, 762, 807
Association of Railway Surgeons, 1134
Climatological Association, 852, 1133
Dermatological Association, 1135
Gastro-enterological Association, 1219
Gastro-enterological Association, seventh annual meeting of the, 665
Gynecological Society, the, 1092, 1097
Institute of Physical Culture, 664
Laryngological Society, 177
Medical Association, the, 1131, 1136, 1152, 1184, 1220
Medical Association—section on materia medica, pharmacy and therapeutics, 1198
Medical Association — section on medicine, 1137, 1184, 1220
Medical Association—section on nervous and mental diseases, 1231
Medical Association—section of obstetrics and diseases of women, 1148, 1194
Medical Association—section on pediatrics, 1150, 1197, 1228
Medical Association—section on surgery and anatomy, 1143, 1189
Medical Association, special clinics for, 900
Medical Colleges, Association of, 1219
Medical Editors' Association, 902
Medical Temperance Association, the, 1039
Neurological Association, 665
Proctologic Society, 903
Society of Clinical Surgery, the, 718
Society of Tropical Medicine, 661
Ammonium sulphate method of sterilizing catgut, the, 934
Amœbæ dysenteriæ, 557
Amputation at the hip-joint for sarcoma of the femur, 406
interscapulo-thoracic, 145
of frozen feet and hands, to receive $10,000 on account of, 851
Anaesthol, 760
Anastomosis for the vas deferens, 407
intestinal, a new device and method for, 40
intestinal, a new method for performing, 199
intestinal, by a new method, 1147
Anatomy and physiology of the peritoneum, the, 422
Anatomy, pathological, 1181
Anchylostomiasis, 183
podophyllin in, 606
treatment of, 750
Andrade, Eduardo, new stain for diphtheria bacilli, 498
Andrews' technic, 1189
Anemia or splenomegaly, types of splenic, 998
pernicious, alterations of the gastro-intestinal canal in, 891
pernicious, of the stomach, 1138
pernicious, spleen in, 1201
splenic, complexity of, 999
Anesthesia in abdominal surgery, 1083
nitrous oxide-ether, 1159
water, 183, 184
water, in surgery, 1174
work, two advantageous procedures in, 255
Anesthetics, 425
Aneurism, aortic, of traumatic origin, 747
of the innominate artery, 1225
popliteal, Matas' operation for, 1145
traumatic, of the subclavian, 30
Aneurisms of the aorta, 209
Angina, syphilitic, 1184
Vincent's, 652
Angiomata, treatment of, 163
Aniline poisoning, 249
Animal heat mechanism, action of morphine on, 213
Animals apparently dead, resuscitation of, 48
Ankle-joint, dislocation of the, 1048
Antenatal rigor mortis, 452
Anthrax bacilli, the capsule of, 938
Antibody from the blood serum of cancer patients, an effort to produce an, 217
Anti-cigarette crusade, an, 368
Antidote for snake bite, 948
Antifat certificates, 616
Antihemolytic properties of the serum of nephrectomized rabbits, 1103
Antimalarial operations, 747
Antimosquito war, 1136
Antipneumococcus serum, 1141
Antistreptococcus serum in articular rheumatism, 210
Antitoxin and diphtheria, 367
as a prophylactic in diphtheria, the value of, 215
for the poor, 567
method of using, 68
plant, establishment of, 269
State manufacture of, in New Jersey, 613
stations, establishment of, 757
treatment of hay fever, 219
tuberculous, internal administration of, 403
Antivivisection in England, the pioneer of, 903
Aorta, etiology of aneurisms of the, 209
and mitral disease, 1186
aneurism of traumatic origin, 747
Aphasia and agraphia, 282
Apocrypha, the physician in the, 179
Apomorphine, elimination of, by the stomach, 71
Apparatus for nitrous oxide-ether anesthesia, 1159
Appendectomy, miliary tuberculosis following, 1104
Appendicitis, a chief predisposing cause of, 1090
acute, and its medical treatment, 883
and influenza, 1224
and pneumonia, 284
an early symptom of severe, 499
chronic, 1213
diagnosis of, 1147
factors in the mortality of, 1147
forensic importance of, 164
in children, 1030, 1147
leucocytosis in, 81
mortality of, 1189
obstruction and distention as a cause of, 845
pathology of, 912

Appendicitis, present status of, 74
symposium on, 46
the mortality of, 49
value of blood count in, 164
Appendix and typhoid, the, 1084
Appointments, 134, 229, 901
medical, at the hospitals in Montreal, 1183
Arctic health resort, an, 367
Army medical reserve corps, proposed, 464
Arsenical poisoning in England, 38
Arsenic habit, 360
therapeutics of, 574
Arteries, resection of, 422
Arteriosclerosis and angina pectoris, 1184, 1185
and infectious disease, 1142
and nephritis, 1142
clinical studies in, 951
earliest sign of, 951
in its relation to life insurance, 947
of spinal cord, 812
pathology of, 1142
serum treatment of, 170
statistics in 4,000 cases, 1142
the dietetic treatment of, 292
under forty-five years, 1143
urine in, 951
Arthritis and endocarditis, experimental, 1001
deformans, 670, 1193
deformans, history of, 1226
deformans, pathology of, 1225
gonorrheal, 1227
Arthropathies of locomotor ataxia, 572
Ascending infection, 670
Ascites, abdominal, with 150 tappings, 640
suture of the omentum to the parietal peritoneum for, 448
